Epoxy esters do not fit the strict definition of alkyd resins, but they are closely related. These resins usually are formed by condensing an unsaturated fatty acid with an epoxy resin of low to intermediate molecular mass (→ Epoxy Resins). Epoxy ester coatings combine part of the toughness, adhesion, and corrosion resistance of epoxies with the easy application and cure of alkyds. They also share the main shortcomings of epoxies: surface chalking when exposed to sunlight and discoloration with age. Epoxy esters are used where their adhesion and corrosion resistance are needed and where surface weatherability is unimportant, for example, in auto body primers and in industrial maintenance paints.

Phenolic modified alkyds are used in applications in which hardness and moisture resistance are important. High-solids formulations have been developed [65].

Rosin and rosin esters (→ Resins, Natural) are used as modifiers mainly to reduce cost. Coating properties are similar to those of chain-stopped alkyds, but films yellow with age and have inferior weatherability. These modifiers are used in wall primers.

5. Low-Solvent Coatings

In most coating processes, the solvent in the coating evaporates into the atmosphere. Formerly the amounts were thought harmless, but by the 1960s it was recognized that the solvents used in alkyd and other coatings contribute substantially to air pollution. In this context, the solvents are called the "volatile organic content" (VOC) of the coating. In air, organic solvents react in a complex photochemical process to produce ozone, one of the most troublesome constituents of photochemical smog.

In the late 1960s and early 1970s governments in many industrial areas adopted "technology forcing" regulations designed to compel coatings users to find ways to reduce VOC emissions. These regulations stimulated research on alkyds during the 1970s and 1980s. Two major approaches were used (→ Paints and Coatings): replacing most of the solvent with water (water-borne coatings), or sharply increasing the proportion of coatings solids to solvent (high-solids coatings). It is estimated that 10 % of alkyd usage is now of the water-borne and high-solids types. The most common approach to water-borne alkyds is to make special alkyds (see below), dissolve them in water-miscible organic solvents, and then add water. These are called "water-reducible" resins. Additional approaches have been introduced more recently, such as solvent-free dispersions of alkyd resins in water. All approaches require substantial changes in conventional alkyd resin technology.

Water Reducible Resins. To make alkyd resins suitable for use in water-reducible paints, it is necessary to chemically change them so they are miscible with blends of water and limited amounts of organic solvent. This is accomplished by attaching hydrophilic sites to the polymer molecules. Numerous procedures for doing so have been published [66–68].The most common method is to place acidic carboxy groups on the molecule and then to "salt" the resin with a base, usually ammonia or an amine. A representative method uses a two-stage process involving trimellitic anhydride [69] (mass parts in parenthesis):

Reduced temperature is used in the second stage to encourage selective reaction of the anhydride group. However, there are several competing side reactions: at 193 °C the anhydride reaction is not completely selective, and acid – ester interchange reactions occur to some degree. For this reason, the process requires careful control to assure consistent product.

If enough carboxyl groups are present to give an acid value of about 45 mg of KOH per gram of resin or higher, the resin forms a transparent mixture when salted and dissolved in 20:80 solvent:water medium. Such resins are sometimes called "water-soluble" alkyds, but their abnormal solution rheology, light scattering, and other evidence indicate that they are seldom, if ever, true solutions. The terms "water-reducible", "water-thinnable", or "water-dilutable" are more descriptive.

Similar resins having acid numbers below about 45 form hazy or milky dispersions when salted and thinned with water. They are often termed "water-dispersible" as well as "water-reducible" alkyds. Such resins are gaining commercial importance because lowering the acid number seems to improve corrosion resistance of the coatings.

Most types of modified alkyds can be made in water-reducible form. For example, water-reducible acrylated [70], silicone-modified [71], and urethane-modified [72] alkyds have been developed.

A disadvantage of this approach is that the ester bond that connects trimellitic anhydride residues to the alkyd resin is more vulnerable to hydrolysis than the ester bonds in most polyesters. For this reason, stability of water-borne paints containing such resins is limited to 3 – 6 months. If a substantial fraction of the crit-

ical ester bond is hydrolyzed, the paint becomes unstable and unusable.

Numerous other approaches to formulating alkyds in aqueous media have been studied, often in efforts to improve package stability. Among the more promising are to copolymerize hydrophilic poly(ethylene oxide) segments into the resin [73], to emulsify hydrophobic alkyds with conventional surfactants [74], to prepare acrylated alkyds in which the acrylic polymer segments contain –COOH or other hydrophylic groups, and to prepare transparent microemulsions [75]. These approaches can be combined. The emulsification approach has been widely studied in recent years [76], [77], and is the basis for commercial products. Careful selection of emulsifiers, pigments, and additives is critical to assure stability and acceptable application characteristics and to avoid adverse interactions that deactivate driers [77].

High-Solids Coatings. There seems to be no standard definition of the term "high-solids coatings". The level of 70 vol % solids has been suggested as a minimum for high solids, but such a definition is arbitrary and does not conform to general usage. In this article, the term is used in a vague but useful way: a high-solids coating is one that is substantially more concentrated than similar coatings that were in general use in the 1960s. For example, an appliance finish that is sprayed at 62 vol % solids is called a high-solids coating because earlier generations were sprayed at 34 %. To emphasize the relative aspect of the definition, some authors prefer the term "higher-solids coatings".

The essential technical problem in formulating high-solids coatings is to find ways to achieve low viscosity without using very much volatile organic solvent. Many formulation and application variables can be manipulated in pursuit of this goal, but the most important is resin viscosity [78]. Therefore, the challenge to the alkyd resin chemist is to reduce the resin viscosity in solution without serious adverse effect on coating properties. To accomplish this difficult task it is necessary to reduce the molecular mass of the resin while increasing its functionality for cross-linking. Especially important is reducing the proportion of soluble high molecular mass molecules in the polymer mixture. These molecules contribute disproportionately to the viscosity [79]; unfortunately, their removal may harm film properties [46]. These difficulties have, to a degree, been overcome, and high-solids alkyd coatings are gaining commercial acceptance.

In air-dry, high-solids alkyds, the most difficult problem is to attain commercially acceptable drying rates without excessive yellowing. Resins that autoxidize very rapidly can be made by use of conjugated or highly unsaturated fatty acids. However, coatings made with such resins tend to turn yellow quickly and to cure too quickly at the surface of the coating film. Surface cure creates an oxygen barrier film that unacceptably slows cure in the interior of the coating. Solutions proposed to solve this problem include use of reactive diluents [80–82], use of auxiliary cross-linkers [83], and use of special autoxidation catalysts [84]. In each case, specially tailored alkyd resins are required.

Alkyds also are used in high-solids baking enamels, where they usually are cross-linked with amino resins, and in two-package alkyd – isocyanate enamels. In both of these applications, alkyds compete with polyester and acrylic high-solids resins.

Ryer presents an overview of new alkyd chemistry and gives several specific formulas [85]. For example, a chain-stopped alkyd suitable for coatings for agricultural and heavy equipment is composed of 72.8 parts (by weight) of soya fatty acid, 44.9 parts of pentaerithritol, 40.0 parts of phthalic anhydride, and 24.4 parts of benzoic acid. Given that the water of reaction is 13.1 parts, one can use Equation (1) to calculate the oil length of this alkyd as 44.8.

Compliance Solvents. In the USA, three solvents, acetone, methyl acetate, and 4-chlorobenzotrifluoride, have been exempted from regulations limiting VOC emissions because of their very low photochemical reactivity. Exemption of one or two more solvents, including *tert*-butyl acetate, is expected. These regulatory changes are very favorable for the future of alkyds, since resourceful formulators can use them to help satisfy air-pollution regulations that limit VOC. Two chlorinated organic solvents, CH_3CCl_3 and CH_2Cl_2, were previously exempted [87] but are little used because of concerns about their safety, corrosiveness, and greenhouse effects.

Latex Modifiers. A few percent of alkyd resin is often added to water-borne architectural paints, the principal binder of which is a polyvinyl or polyacrylic emulsion resin. The alkyd improves adhesion to chalky or oily surfaces. Addition of much larger proportions of alkyd, up to 50 %, is feasible [74], but incentives to commercialize this technology have been lacking because latices have been less expensive than alkyd resins most of the time since 1970.

6. Markets and End Uses

U.S. Tariff Commission states that alkyd resin production in the USA was about $(3-3.5) \times 10^5$ t/a between 1960 and 1980 and then began a slow decline, reaching about 2.3×10^5 t/a by 1996 [25]. The decline is thought to be continuing at a rate of about 2 %/a. Worldwide production figures are not readily available. If the proportion of alkyd used in the rest of the world is the same as in the USA, gobal production would be roughly three times as great as the U.S. figures. The proportion appears to be higher in some major markets, and this suggests that global production may be on the order of 10^6 t/a.

A very high percentage of alkyd production is used in coatings (→ Paints and Coatings). In this market alkyds compete with many other generic types of resins. While they are gradually being displaced by other types of resins, alkyds continue to compete effectively in many end uses. The continuing popularity of alkyds seems to be based on three factors:

1) *Versatility.* Whereas alkyds cannot match the outstanding features of some competing resin types (hardness and weatherability of acrylics, corrosion resistance and adhesion of epoxies, and toughness and abrasion resistance of polyurethanes), they can be formulated to provide a satisfactory balance of properties for many purposes.
2) *Ease of Use.* Well formulated alkyd coatings tend to be easier to apply by spray, brush, or roller than other generic types. They seem less susceptible to popping, sagging, cratering, and other appearance defects. They wet oily or dirty surfaces relatively well. Alkyds are package stable and do not have to be formulated in two-package systems. Air-dry formulations dry quickly, and baking enamels cure at low temperatures. An important but often overlooked factor in the continuing popularity of alkyds is that many existing finishing facilities and procedures have been designed for alkyds, and it has proved difficult to substitute other types of coatings without expensive capital investments.
3) *Economy.* During the 1960s and early 1970s petrochemical monomers, such as acrylics and vinyls, were less costly than the mixture of petrochemical and biomass ingredients used in alkyds. By 1983 the situation had reversed; soybean oil and tall oil fatty acids were selling at less than half the price of basic acrylic monomers. The cost advantage of alkyds is diluted by the petrochemical content of alkyd resins, which averages roughly 50 %, and the need, in most cases, to use petrochemical-based solvents. Since 1983, the relative costs of alkyd resins and 100 % petrochemical-based resins have fluctuated roughly in proportion to the prices of petroleum and of vegetable oils. Soybean oil currently sell for about 0.55 $/kg in the USA, while key vinyl and acrylic monomers (including styrene) sell for 1.5 to 3.5 times as much.

A summary of where alkyds fit in each of the three major coatings market segments follows.

Trade sales, or *architectural coatings*, comprise roughly 52 % of the physical volume and 42 % of the value of coatings sold in the USA. It is estimated that 55 % of the total alkyd usage in paints is in this sector [17][25]. Water-borne formulations based on polyacrylic and polyvinyl emulsion resins have captured over three-fourths of this market in the USA. Their chief advantages are easier cleanup, and better exterior durability. Alkyd- and alkyd – vegetable oil-based paints remain popular with many coating contractors because they can be applied faster and at lower temperatures; emulsion resin paints do not form films properly below about 5 – 8 °C, but alkyds can be used at 0 °C or even lower.

Alkyd-based paints retain a major share of certain trade sales markets, for example, stains, varnishes, high-gloss enamels, and primers. In these market segments, the hard, tough, cross-

linked films of alkyds offer advantages over latices, and their superior adhesion is important.

As noted above, a few percent of alkyd is often added to acrylic emulsion paint formulations to improve adhesion.

Industrial coatings are, by definition, coatings applied at the factory to manufactured goods. They account for roughly 31 % of the volume and 36 % of the value of coatings sold in the USA About 21 % of the alkyds used in paints go into these markets [17], [25].

Alkyd – melamine automotive topcoats have been almost completely replaced by more weatherable acrylic – melamine – formaldehyde and acrylic – polyurethane topcoats. Alkyds still find uses in auto and truck production, for example, in coatings for under-hood parts.

Factory wood finishing is a large user of coatings. Alkyds are used extensively both in alkyd – aminoplast thermosetting enamels and as plasticizers for nitrocellulose lacquers.

Other large-scale manufacturing operations that use alkyds include the following:

1) Metal containers – exterior can finishes
2) Coil coatings – flexible enamels for light fixtures, siding, Venetian blinds, etc.
3) Metal office furniture – hard alkyd – aminoplast enamels
4) Farm implements – fast air-drying enamels

Alkyd coatings are popular in smaller scale factory finishing operations, often because of their ease of application. Examples are tools, fixtures, drums, toys, and shelving. These diverse operations often are called the *general industrial* coatings market; it is a substantial consumer of alkyds.

Special purpose coatings include all organic coatings that do not fit into the above categories. It is a diverse market that is often characterized by sophisticated, specialized coatings. It accounts for the remaining 17 % of the volume and 22 % of the value of U.S. coatings. About 24 % of U.S. alkyd production goes to this segment [17], [25]. Alkyds and modified alkyds share this market with polyacrylic, epoxy, and polyurethane resins. Alkyds are used wherever they are satisfactory because in most cases they are the least expensive and easiest to apply. There are many examples:

1) Highway maintenance – alkyds, thixotropic alkyds, and epoxy esters for bridges, etc.
2) Traffic-control striping – usually very fast drying chain-stopped or styrenated alkyds blended with chlorinated rubber resin; a large market
3) Auto and truck refinish – epoxy ester primers and chain-stopped alkyd topcoats; alkyds losing share to acrylics
4) Marine – alkyds used mainly above the water line; fish oil alkyds popular for rust penetration, silicone alkyds for gloss retention
5) Industrial maintenance – linseed and silicone alkyds for refineries, tanks, factories, etc.

Noncoatings uses. The ink industry is a significant user of alkyd binders, mainly of the longoil isophthalic type. Other uses include caulks, adhesives, sealants, and linoleum. At one time alkyds were used as binders in fiberglass-reinforced plastics, but they have been supplanted almost completely by unsaturated polyesters.

1. Allyl Chloride

Allyl chloride [*107-05-1*], the only chloropropene of industrial importance, was first produced in 1857 by A. Cahours and A. W. Hofmann by reacting phosphorus chloride with allyl alcohol. The name allyl is derived from the latin *allium,* meaning garlic. Inhalation of even small amounts of allyl chloride produces, after a short time, the characteristic odor of garlic on the breath.

At the end of the 1930s, IG Farbenindustrie and the Shell Development Co. developed the high-temperature chlorination of propene, permitting large-scale production of allyl chloride with good yields. A significant part of the development was done by the Shell Chemical Co. when erecting a commercial plant in 1945. Dow, Solvay, and Asahi-Kashima developed their own processes.

1.1. Physical Properties

Allyl chloride, 3-chloropropene, CH_2=CH-CH_2Cl, is a colorless, mobile liquid with a penetrating, pungent odor, M_r 76.53, *mp* −134 °C, *bp* (101.3 kPa) 44.4 °C, n_D^{20} 1.416, n_D^{25} 1.413 [1–5]. Temperature-dependent physical data are given in Table 1.

Expansion coefficient (0 – 30 °C)	0.0041 K^{-1}
Heat of combustion (CH_2=CH-CH_2Cl (g), HCl (g), CO_2 (g), H_2O (g))	1846 kJ/mol
Latent heat of vaporization at *bp*	26 kJ/mol
Critical temperature, t_{crit}	240 °C
Critical pressure, p_{crit}	4.79 MPa
Ratio of specific heat capacities c_p/c_v (at 14 °C)	1.137

Vapor pressure equation

$$\log p = 19.1403 - 2098.0/T - 4.2114 \cdot \log T;$$

$(p \,\mathrm{in\,kPa},\ T \,\mathrm{in\,K})$ [3].

1.2. Chemical Properties

Allyl chloride is a very reactive compound undergoing the usual addition and polymerization reactions at the double bond. Also, because the chlorine atom can be exchanged readily with other groups, allyl chloride is a suitable starting material for the synthesis of a wide range of allyl derivatives.

Reactions of the Double Bond. The reaction of allyl chloride with oxygen in the liquid phase at ca. 120 °C and in the presence of metal acetates or hydrogen peroxide yields glycerol monochlorohydrin. Halogens add readily to the double bond yielding the corresponding trihalogeno compounds. The reaction with hypochlorous acid, yielding 2,3- and 1,3-glycerol dichlorohydrins (which are then dehydrochlorinated with alkali to give epichlorohydrin), is of great industrial importance. Allyl chloride reacts with hydrogen halides to form 1,2-dihalogeno compounds. In the presence of peroxides, the reaction with hydrobromic acid yields 1-bromo-3chloropropane (Kharasch effect), but in highly concentrated hydrogen peroxide solution, 1,2-dibromo-3-chloropropane is formed [6]. Addition reactions of silanes [7], boranes [8], carboranes [9], and phosphorus trichloride [10], as well as cycloadditions of allyl cations with alkenes [11], are known. Allyl chloride polymerizes with sulfur dioxide to form polysulfones [12].

Reactions of the Chlorine Atom. Formerly, the most important reaction industrially was hydrolysis to allyl alcohol, in which small amounts of diallyl ether formed as byproduct. However, today allyl alcohol is produced increasingly by the isomerization of propene oxide (see Section 2.3.2). The chlorine atom is replaced easily by iodide, cyanide, isothiocyanate, sulfide, polysulfides (giving rubber-like condensation products [13]), and alkyl thiols [14]. The salts of carboxylic acids yield allyl esters (e.g., diallyl phthalate), which are easily polymerized to allyl resins or are copolymerized with other monomers. Sodium allyl sulfonate is obtained on reaction with sodium sulfite [15]. The reaction of allyl chloride with ammonia yields a mixture of mono-, di-, and triallylamines [16], [17], and the reaction with primary and secondary amines makes the corresponding alkylallylamines [18]. Organic polycarbonates are formed from a mixture of tertiary amines, sodium carbonate, alkylene glycol, carbon dioxide, and allyl chloride [19]. Phase-transfer-catalyzed carbonylation (e.g., with $Ni(CO)_4$

or $(Me_4N)_2[Ni_6(CO)_{12}]$) in the presence of sodium hydroxide leads to the sodium salt of vinylacetic acid [20], [21]. In the presence of alkalis, allyl chloride reacts with polyols to form the corresponding allyl ethers. Further reactions are described in [22].

1.3. Production

1.3.1. Chlorination of Propene

Allyl chloride is produced on a large scale by the high-temperature (300 – 600 °C) chlorination of propene:

$$CH_2{=}CH\text{-}CH_3 + Cl_2 \rightarrow CH_2{=}CH\text{-}CH_2Cl + HCl \qquad \Delta H^0_{298} = -113\ \text{kJ/mol}$$

At these temperatures, chlorination proceeds by a free-radical chain mechanism, whereby the hydrogen atom in the allyl position is substituted preferentially by the chlorine, giving allyl chloride [23].

Byproducts. Below 200 °C propene reacts with chlorine mainly by addition to the double bond to give 1,2-dichloropropane; above 300 °C, this reaction is suppressed and the formation of allyl chloride predominates so that 1,2-dichloropropane is only a byproduct. The compounds *cis*- and *trans*-1,3-dichloropropene arise from a secondary reaction of allyl chloride, in which a further hydrogen atom is substituted by chlorine. Small amounts of other chlorination products are formed also:

$$CH_3{-}CH{=}CH_2 + Cl_2 \rightarrow CH_3{-}CHCl{-}CH_2Cl \qquad \Delta H^0_{298} = -184\ \text{kJ/mol}$$

$$ClCH_2{-}CH{=}CH_2 + Cl_2 \rightarrow CH_2Cl\text{-}CH{=}CHCl + HCl \qquad \Delta H^0_{298} = -101\ \text{kJ/mol}$$

$$CH_3{-}CH{=}CH_2 + Cl_2 \rightarrow CH_3{-}C(Cl){=}CH_2 + HCl \qquad \Delta H^0_{298} = -121\ \text{kJ/mol}$$

$$CH_3{-}CH{=}CH_2 + Cl_2 \rightarrow CH_3{-}CH{=}CHCl + HCl$$

The most important variables in the industrial chlorination process of propene to allyl chloride are the temperature and the ratio of propene to chlorine, whereas pressure and residence time have only a slight effect on the allyl chloride yield [24]. Because the dominant reaction below 200 °C is addition to form 1,2-dichloropropane, the mixing temperature of propene and chlorine must be kept above 250 – 300 °C. The best yields of allyl chloride in industrial reactors are obtained at a maximum reaction temperature of 500 – 510 °C. If the reactor temperature is increased further, spontaneous pyrolysis occurs, with the formation of soot and high-boiling tars. Under laboratory conditions and temperatures of ca. 600 °C, benzene is formed and the yield of allyl chloride decreased [24], [25].

The *maximum reaction temperature* can be influenced by the temperatures of propene and chlorine entering the reactor and by the ratio of propene to chlorine. In general, only the propene is preheated. If the chlorine is also preheated, expensive construction materials must be used to avoid the danger of a "chlorine fire." For a given propene: chlorine ratio, the preheating temperature of the propene is fixed; for example, for $C_3H_6 : Cl_2 = 3$ the temperature is set at ca. 300 °C and for $C_3H_6 : Cl_2 = 5$, at ca. 400 °C [24].

Propene : Chlorine Ratio. The formation of byproducts decreases with increasing propene excess [26]. On the other hand, the cost of processing the propene rises simultaneously. The optimum reaction conditions are therefore strongly influenced by economic considerations, including the demand for the dichloride byproducts as nematocides [27]. The byproducts can be employed also as starting material for the production of C_1- or C_2-type solvents.

The *pressure* in the reactor has little influence on the yield or the distribution of products and is determined only by the pressure drop in the propene circulation system of the plant.

The *residence time* has only a small effect on the yield of allyl chloride. At high temperatures (300 – 600 °C), the chlorine has completely reacted after 1 – 3 s [24]. Too long a residence time, however, leads to thermal decomposition of the allyl chloride [25].

Reactor Construction. Industrial-scale reactors mainly operate adiabatically, even though higher yields would be expected when operating isothermally. Because the reaction is rapid and exothermic, the amount of heat lost through the reactor wall is not significant.

The technically simplest and oldest reactor type is the tube reactor, which sometimes is equipped with facilities for gas distribution and soot removal [25]. Many other reactor designs are known [26], [28–35], but all reactors are designed to achieve the mixing of the two reactants as rapidly and as thoroughly as possible in order to reduce the secondary reaction to form 1,3-dichloropropene. Under the good mixing conditions obtained in a highly turbulent flow, propene and chlorine are fed into the reaction zone at velocities up to 300 m/s. The importance of optimum mixing conditions is demonstrated by a cyclone reactor, in which, at a molar ratio of 3 : 1, similar yields are obtained as at a ratio of 5 : 1 with other designs [36]. Many reactors are equipped with a cooling jacket.

If the chlorine is distributed among several reactors arranged in a cascade, a chlorine conversion of up to 86 % can be achieved [37], [38]. With this arrangement, higher preheating temperatures are possible because of a higher propene : chlorine ratio in the first reactor.

In another design of a cascade of reactors only the first reactor is charged with preheated propene and chlorine. Liquid propene and gaseous chlorine (molar ratio of 1 : 1) are fed into the other reactors. The advantages of this procedure are the cooling of the reaction gas and a quasiconstant ratio of the reactants over all stages. At an overall molar ratio of 3.2 : 1, the same yield is achieved as at a ratio of 7 : 1 in a single reactor [39].

Feed Preparation. The *purity* of the propene and the chlorine is important. Organic impurities in the propene cause the formation of byproducts and loss of chlorine. Especially propane leads to the formation of chlorine derivatives (1-chloropropane, 2-chloropropane) which are difficult to separate. Polymer-grade propene with a purity of 99.5 % often is employed as the feedstock. The use of revaporized chlorine insures adequate purity. Small amounts of inert gases are thereby introduced into the process, the venting of which means propene losses. Both raw materials must contain as little water as possible. This is a particularly important condition for the choice of materials for the various stages of the plant (see below).

A process similar to that employed by Shell, for example [24], [40], is shown in Figure 1. Liquid propene is vaporized, then preheated to 350 – 400 °C (b), and fed, together with gaseous chlorine, into the reactor (c) via a mixing jet. The chlorine reacts completely, thereby increasing the temperature to 500 – 510 °C (under optimum conditions). Even under the best conditions, small amounts of carbon are formed; these catalyze the chlorination. A protective film of vitreous carbon deposits on the reactor walls. This material, which also contains highly chlorinated materials and tar, must be cleaned from the reactor walls at intervals of 4 – 8 weeks. Two parallel reactor chains often are in use so that partial production can be maintained during the cleaning. Another possibility is alternate operation of the two chains.

The gas stream leaving the chlorination reactor is precooled (d) and led to a prefractionator (e), the overhead temperature of which is maintained at ca. – 40 °C by feeding liquid propene. This effectively separates all chlorinated hydrocarbons; the bottom product is free of propene and hydrogen chloride.

The gaseous mixture drawn off overhead is separated by absorption with water (i) into aqueous hydrogen chloride of commercial quality and propene. Then the propene is washed with caustic soda in a scrubber (k) to remove traces of hydrogen chloride. After compression to 1.2 MPa (12 bar), it is liquefied in a condenser (l, q). Water is separated (m) and liquid propene is dried by adsorption (n) and returned to the storage tank (a).

The bottom product of the prefractionator contains 80 % allyl chloride, 3 % 2-chloro-1-propene [*557-98-2*] and other low boilers, 16 % dichlorides (mainly 1,2-dichloropropane [*78-87-5*] and *cis*- and *trans*-1,3-dichloro-1-propene [*542-75-6*]), and 1 % 1,2,3-trichloropropane [*96-18-4*] and other heavy boilers [40]. These four fractions are separated by distillation (f, g, h).

The basic principle of most production processes is as shown in Figure 1, although it has been modified for the synthesis and the fractionation processes [41–44]. For example, cooler (d)

in Figure 1 can be replaced by quench cooling [44], whereby the hot reaction gases are cooled by the evaporation of propene or of condensed reaction products.

Construction Materials. The choice of materials in the allyl chloride synthesis (propene circulation) depends on the individual process operations, temperature, and pressure. In principle, normal carbon steel is resistant where the water content of the product streams is low enough. If the chlorine stream is not preheated, carbon steel also can be utilized in the reactor area. However, materials resistant to chlorine at high temperatures (chromium – nickel steels, nickel, cupronickel alloys) often are employed in the reactor region. Graphite and PTFE coatings are favored for the absorption of the hydrogen chloride, whereas rubberized steel can be employed for the caustic soda scrubber. Carbon steel is suitable for the entire chlorinated hydrocarbon fractionation plant. However, in places when large amounts of water are present, expensive materials, such as nickel and cupronickel, are necessary [45]. Dry allyl chloride can be stored in steel vessels without any danger of corrosion.

1.3.2. Other Production Processes

Several other processes have been suggested for the production of allyl chloride, but none of these has been operated commercially.

Catalytic Chlorination of Propene. This process uses tellurium-containing catalysts [46]; allyl chloride yields of up to 82 % are obtained. The main organic byproduct is 17 % 2-chloropropane (isopropyl chloride). Unreacted propene and the hydrogen chloride produced in the reaction can be converted to allyl chloride in a second reaction step by oxychlorination.

The dehydrochlorination of 1,2-dichloropropane [47–49] produces only a 55 % yield of allyl chloride plus a large amount of monochloropropenes. The process is of no commercial interest even though the starting material is dichloropropane, produced in large quantities during the production of propene oxide.

Oxychlorination. Oxichlorination was developed for the production of allyl chloride in order to utilize cheaply available hydrogen chloride instead of chlorine as the feedstock [50–62]. Palladium, vanadium, tellurium, copper, lithium, and manganese, as well as their chlorides and oxides and mixtures thereof, have been suggested as catalyst systems.

Most of these oxychlorination processes start from propene [50–60], although two of them start from propane [61], [62]. The following process was tested in a pilot plant by Hoechst [58].

Propene, hydrogen chloride, oxygen, and 2-chloropropane (either produced in a subsidiary reactor or introduced from outside) react in a main fluid-bed reactor at 200 – 260 °C and 0.1 MPa (1 bar) gauge pressure ($\Delta H = -218$ kJ/mol). The carrier catalyst contains tellurium, vanadium pentoxide, phosphoric acid, and a nitrogen compound as promoter. A part of the catalyst flow is treated in a side stream with air and nitric acid to remove coke and maintain constant reactivity. In a subsidiary reactor, 2-chloropropane is produced from propene, hydrogen chloride, and ferric chloride solution. The unreacted propene, 2-chloropropane, and hydrogen chloride are separated and recycled. The yield of allyl chloride is 88 – 94 % based upon propene. The purity of the propene is not particularly critical.

Some of the suggested oxychlorination processes have disadvantages. For example, the activities of the catalysts deteriorate quickly as a consequence of the volatility of the metal salts employed and large volumes must be passed through the reactor because the conversion per pass is low. Also, it is difficult to remove the highly dilute allyl chloride from the reaction mixture without excessive loss of propene by reaction with oxygen. A suggestion [60] attempts to avoid these disadvantages by using manganese dioxide as both catalyst and carrier for oxygen. The following reactions take place in the main reactor:

$$MnO_2 + 4\,HCl \longrightarrow MnCl_2 + Cl_2 + 2\,H_2O$$

$$C_3H_6 + Cl_2 \longrightarrow C_3H_5Cl + HCl$$

The catalyst is then reoxidized and activated with oxygen:

$$MnCl_2 + O_2 \rightarrow MnO_2 + Cl_2$$

Figure 1. Allyl chloride production by high-temperature chlorination of propene
a) Storage vessel for liquid propene; b) Evaporator and superheater for propene; c) Reactor; d) Cooler; e) Prefractionator; f) Light-ends column; g) Allyl chloride purification column; h) Dichloropropene column; i) Hydrogen chloride absorber; k) Gas washer; l) Compressor; m) Decanter for removing water; n) Propene dryer; p) Evaporator; q) Condenser; r) Cold propene storage vessel

The process achieves an allyl chloride yield of between 71 and 81 % based on the consumption of propene.

1.4. Handling, Environmental Protection, Storage, and Transportation

Handling and Environmental Protection. Allyl chloride is a highly reactive, highly toxic, easily ignitable substance. Therefore, very stringent standards exist in many countries for atmospheric emission. Allyl chloride should be handled in closed systems in order to fulfill these requirements. Gases containing allyl chloride or byproducts of the production process must be purified by condensation in cold traps, by absorption, by adsorption, or in special cases by combustion before they are vented [63]. The compensation technique has proved of value during transfer from one vessel to another.

Any contamination of the soil, of underground water supplies, watercourses, or of wastewater must be avoided. Any danger of such contamination must be reported immediately to the responsible authorities.

Allyl chloride-containing wastes can be disposed of without difficulty in special incinerators, such as those used for the disposal of solvents, where the combustion gases are treated in absorbers or scrubbers to remove the hydrogen chloride formed.

Because of the high volatility and low flash point of allyl chloride, plants for its production and processing must comply with the relevant standards for fire and explosion protection.

Combustion of chlorinated hydrocarbons produces hydrogen chloride, so that fire fighters should be equipped with suitable protective suits and portable breathing apparatus. Combustion in the absence of adequate air supplies can lead to the formation of carbon monoxide.

Allyl chloride is highly reactive. Therefore contact with other substances can lead to vigorous, exothermic, and even explosive reactions. This applies particularly to alkali and alkaline-earth metals, but also to aluminum and zinc and to strong oxidizing agents, such as concentrated sulfuric acid. The anhydrous halides (e.g., chlo-

rides) of the metals mentioned above also react vigorously with allyl chloride [5]. In plants producing or processing allyl chloride, careful consideration must be given to the safety aspects of these exothermic reactions [64]. In 1996, allyl chloride has been classified by the EC as "dangerous for the environment" and "very toxic to aquatic organisms".

Storage. Pure, dry allyl chloride (water content $\leqq$ 200 mg/kg) does not corrode iron and can be stored in ferrous containers for months at ambient temperatures without significant changes in quality. Lined vessels should be used if traces of iron chlorides are objectionable. Unwanted coloration can be prevented by the addition of a suitable stabilizer (e.g., propene oxide).

Transportation of the highly toxic and highly flammable allyl chloride is governed by many regulations [65]. International marine transportation is governed by the IMDG Code, D 3108, class 3.1, UN no. 1100; transportation in Europe is governed by RID, ADR, and ADNR class 6.1, no. 4 a, Rn 601, 2601, and 6601, respectively. European Economic Community: Yellow Book 78/79, EG-no. 602–029–00-X; Great Britain: Blue Book: Flammable Liquid, IMDG Code E 3023; United States: CFR 49: 172 – 189, Flammable Liquid (DOT Regulations) [5].

The most important regulations state that:

1) Vessels may be filled only to a maximum of 93 % of their volumes or the RID (Suppl. X and XI) must be complied with.
2) Road transport is allowed (in Germany a maximum of 3 t per tank container).
3) No pipe ducts or pipe connections are allowed below the surface of the liquid. Filling and emptying connections must be tightly closed and should be additionally secured by means of sealed caps. The tanks must be tested regularly to insure that they withstand total pressures of 0.6 MPa (6 bar).
4) Welded drums constructed of steel or stainless steel must be used for transport in drums. Frequent changes in regulations are recorded. Each transport must be examined individually with regard to the countries concerned.

1.5. Quality and Analysis

Commercial allyl chloride is at least 97.5 wt% pure and contains 1-chloropropene, 1-chloropropane, and 1,5-hexadiene as impurities. In addition, it contains a stabilizer, such as propene oxide, to scavenge any hydrogen chloride produced hydrolytically on long-term storage. Allyl chloride containing traces of iron has a pinkish tinge. The quantitative analysis of allyl chloride is performed exclusively by gas chromatography.

1.6. Uses

Allyl chloride [22], [66] is an important intermediate in the petrochemical industry, used chiefly for the production of epichlorohydrin, which in turn is used in the production of epoxy resins. Allyl chloride is a starting material in the synthesis of various chemicals, such as glycerol, many esters [of which those of phthalic, phosphoric, and carboxylic acids are the most important (Section 3.2.4)] and some allyl ethers (Section 4.2) and allylamines (Section 5.2).

Further compounds made from allyl chloride are: *allyl isothiocyanate* (synthetic mustard oil), used in plant protection agents and pharmaceutical preparations; *allyl sulfonate,* used as an electroplating-bath additive [67] and in the production of carbon fibers [68]; *allylsilane,* used for the production of additives for the rubber industry; and *cyclopropane,* an anesthetic.

1.7. Economic Aspects

More than 90 % (ca. 800 000 t worldwide in 1997) of the allyl chloride produced is used for the production of epichlorohydrin. Less than 55 000 t worldwide went into other applications.

2. Allyl Alcohol

Allyl alcohol was first prepared in 1856 by A. Cahours and A. W. Hofmann by saponification of allyl iodide. For general literature on allyl alcohol, see [69–74].

2.1. Physical Properties

Allyl alcohol [*107-18-6*], 2-propen-1-ol, CH_2=CH-CH_2OH, C_3H_6O, M_r 58.08, *mp* − 129 °C, *bp* 96.9 °C (101.3 kPa), is a colorless, mobile liquid with an irritating odor.

Allyl alcohol is miscible with water and organic solvents in all proportions at 20 °C. Table 3 contains the most important azeotropic data for binary and ternary allyl alcohol azeotropes.

2.2. Chemical Properties

The allylic hydroxyl group and the olefinic double bond can undergo numerous reactions, such as oxidation, reduction, hydrogenation, condensation (formation of ethers and esters), and addition. At room temperature, allyl alcohol is a stable liquid. When heated to temperatures above about 100 °C, allyl alcohol forms water-soluble polymers (polyallyl alcohols) that react with alkenoic acids to give drying oils [75].

Allyl alcohol also can be grafted to polyimides [76] or copolymerized with styrene in the presence of oxygen [77]. Condensation of allyl alcohol with methyl glucoside polyethers, followed by bromination and addition of isocyanates, yields flame-resistant polyurethane foams [78].

Hydroxylation. The reaction of allyl alcohol with hydrogen peroxide in the presence of catalytic amounts of tungstic acid yields glycerol with excellent selectivity (→ Glycerol). This commercially important process was developed by Shell [79]. The hydroxylation of allyl alcohol can be carried out also by organic hydroperoxides, such as ethylbenzene hydroperoxide, in the presence of a vanadium catalyst [80]. Organic hydroperoxides oxidize allyl alcohol selectively to glycidol (oxiranylmethanol) [*556-52-5*] [81]. Glycidol is also obtained by the reaction of allyl alcohol with peracids [82].

Allyl alcohol can be *dehydrogenated* with air in the gas phase over palladium, silver, or copper catalysts to give acrolein [83], [84]. The *oxidation* of allyl alcohol in the liquid phase (150 – 200 °C, Pd catalyst) yields acrylic acid and acrolein with 83 % combined selectivity [85].

Catalytic *hydrogenation* of allyl alcohol gives 1-propanol [*71-23-8*] [86]. *Chlorination* in aqueous solution yields mono- and dichlorohydrins of glycerol, which can be hydrolyzed to glycerol [87]. *Bromination* proceeds very selectively in aqueous solution, buffered by calcium chloride [88]; 2,3-dibromo-1-propanol [*96-13-9*], used in flame-resistant materials [89], is formed.

Allyl alcohol reacts with allyl chloride to give diallyl ether [*557-40-4*] (*bp* 94 °C) and with methallyl chloride to give allyl methallyl ether [*14289-96-4*]. Carbon tetrachloride adds to allyl alcohol by radical initiation, leading to 2,4,4,4-tetrachloro-1-butanol [*3290-70-8*], which is a useful intermediate in flame-retardant technology [90].

Hydroformylation of allyl alcohol in the presence of cobalt carbonyl yields 4-hydroxybutyraldehyde [*25714-71-0*] [91] in 30 % yield. With rhodium-complex catalysts, the 4-hydroxybutyraldehyde yield is improved to 80 % [92].

The aldehyde then can be hydrogenated to 1,4-butanediol (→ Butanediols, Butenediols, and Butynediols), a useful monomer for the production of polyurethanes [93]. When the hydroformylation of allyl alcohol is carried out in the vapor phase over rhodium triphenylphos-

phine complexes on porous carriers, tetrahydro-2-furanol [*5371-52-8*] is obtained in 94 % yield [94]. Carbonylation of allyl alcohol in acetic acid solution with a palladium chloride catalyst gives 3-butenoic acid [95].

2.3. Production

The raw material in all commercial processes is propene. However, although allyl alcohol can be made via a variety of intermediates, only the processes proceeding via allyl chloride and propylene oxide are of major commercial importance.

2.3.1. Hydrolysis of Allyl Chloride

Allyl alcohol is produced commercially by Shell and Dow from allyl chloride [24], [26]. Allyl chloride is hydrolyzed by a 5 – 10 % sodium hydroxide solution at 150 °C and 1.3 – 1.4 MPa, yielding 85 – 95 % allyl alcohol. Byproducts are diallyl ether (5 – 10 %), chloropropenes, propionaldehyde, and high-boiling material. In order to obtain commercially satisfactory yields of allyl alcohol, it is necessary to mix the allyl chloride thoroughly with the aqueous alkaline solution, maintaining a constant pH value. The allyl chloride has to be converted nearly quantitatively, because its high corrosiveness does not allow economical recovery. The reaction therefore is carried out in a recycle reactor; the most suitable reactor material is nickel.

A commercial plant for the production of allyl alcohol by continuous allyl chloride hydrolysis [24] is shown in Figure 2. Water is removed from the raw allyl alcohol by azeotropic distillation with diallyl ether as entrainer.

For some reactions, the raw allyl alcohol – water azeotrope (72 % allyl alcohol) may be used without further purification.

2.3.2. Isomerization of Propene Oxide

The catalytic rearrangement of propene oxide is of increasing commercial interest and has partially replaced the hydrolysis of allyl chloride. The most commonly used catalyst is lithium phosphate.

Vapor-Phase Process. Propene oxide vapor passes at 250 – 350 °C over a lithium phosphate catalyst containing up to 30 % inert material. The catalyst is arranged in a fixed bed. Conversions are about 70 – 75 %; allyl alcohol selectivity is 97 %. Space-time yields of 0.5 kg allyl alcohol per liter of catalyst per hour are obtained. Olin Mathieson uses a lithium phosphate catalyst which contains 1 % alkali hydroxide and which has to be regenerated after 40 h by washing with acetone [96]. The catalyst developed by Chemische Werke Hüls [97], containing 73.6 % lithium phosphate and 17.5 % silica, needs no regeneration. Even after 1200 h, an allyl alcohol selectivity of 97.3 % is maintained. Lithium arsenate also has been proposed as an isomerization catalyst but has no essential advantage over lithium phosphate [98]. An older, chromium oxide-catalyzed process, developed

Figure 2. Allyl alcohol production
a) Preheater; b) Hydrolysis reactor with recycle system; c) Stripping column; d) Dehydration column; e) Separator; f) Diallyl ether washing tank; g) Allyl alcohol purification column

by Wyandotte Chemical Corp. [99], gives much lower conversions and selectivities.

Liquid-Phase Process. The Progil process [100] is carried out with a finely ground lithium phosphate catalyst suspended in high-boiling solvents, such as terphenyl or alkyl benzenes. Propene oxide is bubbled through the suspension at 280 °C. Conversion is 60 %, allyl alcohol selectivity 92 %, and the space-time yield 1 kg allyl alcohol per liter per hour. Catalyst lifetimes of 500 – 1000 h are achieved. Jefferson Chemical Co. patented a similar process using a mixture of biphenyl and diphenyl ether as solvent [101].

2.3.3. Hydrolysis of Allyl Acetate

Propene, acetic acid, and oxygen react in the gas phase over palladium catalysts to form allyl acetate, which in turn is hydrolyzed to allyl alcohol:

$$C_3H_6 + CH_3COOH + 1/2\,O_2 \xrightarrow{Pd} CH_2{=}CHCH_2OCOCH_3 + H_2O$$

$$CH_2{=}CHCH_2OCOCH_3 + H_2O \rightarrow CH_2{=}CHCH_2OH + CH_3COOH$$

$$C_3H_6 + 1/2\,O_2 \rightarrow CH_2{=}CHCH_2OH$$

The acetic acid is recovered and reused in the oxidation of propene. Therefore, only propene and oxygen are required as raw materials for the preparation of allyl alcohol.

This process needs no chlorine and therefore may be of commercial interest in the future. Allyl acetate can be hydrolyzed by heating at about 230 °C and 3 MPa, according to a process developed by Hoechst [102], [103]. In the Bayer process hydrolysis is carried out catalytically over an acid cation exchanger (sulfonated polystyrene) at 100 °C [104], [105]. The overall yield of allyl alcohol, relative to the propene feed, is 90 %.

2.3.4. Hydrogenation of Acrolein

Allyl alcohol also can be obtained by catalytic hydrogenation of acrolein in the vapor phase. Use of cadmium – zinc catalysts gives yields up to 70 % [106]. The hydrogenation also can be carried out over silver – cadmium alloys on inert carriers, such as alumina or silica, also giving yields up to 70 % [107].

Ethanol or isopropyl alcohol can reduce acrolein to allyl alcohol in the presence of a mixture of magnesium oxide and zinc oxide [108], [109]. The reaction takes place in the vapor phase at 400 °C; allyl alcohol yields of 80 % have been reported [108].

2.4. Quality and Analysis

Commercial allyl alcohol has the following specifications: content of allyl alcohol 98.0 wt % (minimum), content of water 0.3 wt % (maximum), boiling range 95 – 98 °C. The purity of allyl alcohol is determined by GC. In the absence of saturated alcohols, allyl alcohol can be determined also by acetylation with *N*-acetylpyridinium chloride and back titration of the unconverted *N*-acetylpyridinium chloride. Water is determined by Karl Fischer titration.

2.5. Uses

Allyl alcohol is an intermediate in the production of polymerizable allyl ethers and esters, especially diallyl phthalate. The bulk of the allyl alcohol produced commercially is consumed in the production of glycerol. Polymeric allyl alcohol reacts with unsaturated fatty acids to give drying oils [75]. Sulfur dioxide and allyl alcohol yield polymeric allylsulfonic acids, which have been proposed as intermediates for plasticizers and textile auxiliaries [110]. Allyl alcohol can be copolymerized with other monomers [76], [77] and then used as an intermediate in the production of flame-resistant materials [78], [89], [90] or as a nematocide, fungicide, or preservative.

2.6. Methallyl Alcohol

Methallyl alcohol [*513-42-8*], 2-methyl-2-propen-1-ol, $CH_2{=}C(CH_3)\text{-}CH_2OH$, C_4H_8O, M_r 72.11, *bp* 114.5 °C (101.3 kPa), d_4^{20} 0.8515, n_D^{20} 1.4255, is only partially miscible with water (19.4 wt % methallyl alcohol in water, 33.8 wt % water in methallyl alcohol, at 20 °C). The methallyl alcohol-water azeotrope (*bp* 92 °C) contains 59.8 wt % methallyl alcohol.

Methallyl alcohol is prepared by hydrolysis of methallyl chloride in a 10 wt % aqueous sodium hydroxide solution [111], [112]. Pure methallyl alcohol can be obtained by methanolysis of methallyl acetate in the presence of catalytic amounts of bases [113]. Methallyl alcohol is used in the preparation of polymerizable esters.

3. Allyl Esters

3.1. Properties

Physical Properties. The lower allyl esters, such as allyl acetate, methallyl acetate, and allyl acrylate, are colorless, mobile liquids of low viscosity, with pungent odors, which cause violent irritation of the mucous membranes. The higher allyl esters, such as diallyl phthalate, have high viscosities and boiling points and are nearly odorless. The physical properties of the commercially most important allyl esters are summarized in Table 4.

Chemical Properties. Industrially, the most important property of allyl esters is their ability to polymerize in the presence of oxygen or peroxides. The allyl esters readily undergo hydrolysis and transesterification. Allyl acetate can be oxidized by oxygen and acetic acid over a palladium catalyst to 2-propene-1,1-diol diacetate [*869-29-4*] [114].

Addition of chlorine in the presence of catalytic amounts of transition-metal chlorides yields 2,3-dichloro-1-propanol acetate [*589-96-8*] [115]. Acetic acid can add to allyl acetate in the vapor phase (phosphoric acid catalyst, 200 °C) [116] or in the liquid phase with cation exchangers as catalysts [117], yielding 1,2-propanediol diacetate [*623-84-7*].

Substitution. Hydrogen chloride converts allyl acetate to allyl chloride; the reaction takes place at 100 °C in the liquid phase. A combination of copper(I) chloride and iron(III) chloride which is soluble in allyl acetate, is used as a catalytic system [103], [118], giving conversions of allyl acetate up to 94 %, and an allyl chloride selectivity of 96 %. Over copper catalysts, hydrocyanic acid converts allyl acetate to allyl cyanide (3-butenenitrile) [*109-75-1*] [119–121].

Hydroformylation of allyl acetate creates a mixture of acetoxybutyraldehydes [91], [122], [123], the main product being 4-acetoxybutyraldehyde [*6564-95-0*] in yields of about 70 %. This aldehyde is an intermediate in a proposed production method for 1,4-butanediol and butyrolactone.

Table 4. Physical data of important allyl esters

	CAS Registry No.	Mol. Formula, M_r	*bp*, °C/*p*, kPa	d_4^{20}	n_D^{20}

[c] at 25 °C

Allyl acetate can undergo a metathesis reaction leading to 2-butene-1,4-diol diacetate (*cis*- and *trans*-isomers) [*18621-75-5*] and ethylene. With a catalyst system consisting of rhenium heptoxide on alumina promoted by tetramethyltin [*594-27-4*], allyl acetate conversions of 17 % are obtained. The selectivity for 2-butene-1,4-diol diacetate is 96 % [124].

3.2. Production

3.2.1. Oxidation of Olefins

Vapor-phase oxidation of olefins in the presence of lower alkanoic acids and over palla-

dium catalysts yields the corresponding alkenyl esters.

The olefins are attacked in the allylic position. For example, propene is oxidized in the presence of acetic, propionic, or butyric acid to give allyl acetate, allyl propionate, or allyl butyrate, respectively. In a similar way, the methallyl esters are obtained by oxidation of isobutene.

Allyl Acetate. Propene is oxidized with oxygen in the presence of acetic acid in a tubular reactor [125–127]. The solid catalyst is located in a plurality of tubes and contains metallic palladium, alkali acetate, and promoters, such as compounds of iron or bismuth [125], [126]. The reaction takes place in the vapor phase at 50 – 250 °C and elevated pressure. Because of the high exothermicity of the reaction ($\Delta H = -1890$ kJ/mol) and to avoid explosion hazards, propene and acetic acid are converted only partially. The Bayer process [125], [128] yields allyl acetate with selectivities higher than 90 mol%, carbon dioxide being the sole byproduct.

Methallyl acetate is produced from isobutene, acetic acid, and oxygen by a similar process [129].

Liquid-Phase Oxidation. Olefins can be oxidized also in the liquid phase with a catalyst system consisting of palladium chloride and copper(II) chloride (redox system) [130]. This reaction is not selective; major byproducts are 1-propene-1-ol acetate, 1-propene-2-ol acetate, propionaldehyde, and acetone.

3.2.2. Esterification

A general method for the preparation of allyl esters is the reaction of allyl alcohol with the free acids, acid anhydrides, or acid chlorides. Catalysts frequently used are aromatic sulfonic acids (*p*-toluenesulfonic acid and naphthalene-2-sulfonic acid) [128]. Strong mineral acids are of less value because they can decompose the allyl alcohol. Polymerizable acids are esterified in the presence of phenolic inhibitors. The following allyl esters are prepared by this method: *diallyl phthalate*, *diallyl isophthalate*, *diallyl maleate*, *diallyl fumarate*, *triallyl cyanurate* (from cyanuric chloride and allyl alcohol), and *diethylene glycol bis*(*allyl carbonate*). The last of these compounds is obtained from allyl alcohol and the corresponding bischloroformate (prepared from diethylene glycol and phosgene).

3.2.3. Transesterification

Higher allyl esters can be prepared by transesterification of the corresponding methyl esters with allyl alcohol; sodium methanolate is the preferred catalyst [131], [132]. *Diallyl phthalate* and *diallyl sebacate* can be prepared in this way. The transesterification of methyl or ethyl esters with allyl acetate has been proposed [133], [134]. This method would be of industrial interest if allyl acetate were commercially available as a primary product, for example, by oxidation of propene [133]. Suitable transesterification catalysts are alkoxides or alkoxide complexes of elements of the first to third main groups of the periodic table or alkoxides of titanium and zirconium [134]. The ester is mixed with twice as much allyl acetate and catalytic amounts of the alkoxides and heated to reflux temperature. Methyl acetate (*bp* 57 °C) and ethyl acetate (*bp* 77 °C) have the lowest boiling points and are removed from the equilibrium by distillation. The desired allyl ester can be isolated in excellent yields and high purity.

3.2.4. Other Production Methods

The reaction of allyl chloride with the alkali salts of mono- or dicarboxylic acids to give the corresponding allyl esters is well known. These salts also may be formed during the reaction. In this way, *diallyl phthalate* is obtained from the reaction of allyl chloride and phthalic anhydride in the presence of sodium hydroxide, sodium carbonate, tertiary amines, or quaternary ammonium salts [135].

Allyl acrylate is prepared by the pyrolysis of allyl lactate, *allyl methacrylate* in a similar manner from allyl 2-hydroxyisobutyrate [136]. *Substituted tetrahydrophthalic acid allyl esters* are obtained by Diels-Alder reaction of the corresponding substituted butadienes and diallyl maleate [137]. The best method for the preparation of *triallyl phosphate* is the condensation of phosphorus trichloride with allyl alcohol to give *triallyl phosphite* [*102-84-1*] followed by oxidation with air [138]. *Diethylene glycol bis*(*allyl*

carbonate) can be prepared in 87 % yield by heating allyl chloride, diethylene glycol, and carbon dioxide in the presence of sodium carbonate and triethylamine in an autoclave [139].

3.3. Uses

3.3.1. Polymer Production

Polymer production is the most important application of allyl esters. They are especially suitable as components in copolymers. Some allyl esters are used for cross-linking or curing of polyolefins (graft copolymerization). Optimum cross-linking is obtained by adding specific peroxides or by high-energy irradiation. The cross-linked polymers and copolymers of allyl esters give thermoset articles of excellent heat resistance. Other applications of these polymers are in the production of casting sheets, molding material, electric and optical devices of high resistance, and flame-retardant materials.

Diethylene glycol bis(allyl carbonate) usually is referred to as *CR 39 monomer*. It is bulk polymerized by the addition of relatively large (compared to similar polymerizations) amounts of peroxides. The commercially preferred peroxide initiator is isopropyl percarbonate [*105-64-6*]. The homopolymer (*CR 39 polymer*) [*25656-90-0*] is suitable for the production of cast sheets, lenses, and other articles that have excellent resistance to scratching, impact, and heat as well as outstanding optical properties [140–142]. This polymer is resistant to common solvents with the exception of oxidizing acids. It is produced in the United States by PPG Ind. [140]. Even better qualities can be obtained by reacting CR 39 monomer with other monomers, such as methyl methacrylate [*80-62-6*] or triallyl isocyanurate [*1025-15-6*]. These copolymers are used for the production of light-weight lenses with very hard surfaces and high refractive indices [143].

Diallyl phthalate is an important monomer for the production of thermosetting molding compounds, which must have good dimensional stability and electrical properties, and be resistant to heat and solvents. Diallyl phthalate can be polymerized or copolymerized. The preferred technique is first to prepare a prepolymer or precopolymer in solution. This usually is done by dissolving the diallyl phthalate monomer in 2-propanol, adding 50 % hydrogen peroxide at about 105 °C, and precipitating the prepolymer from the cooled, viscous solution with excess 2-propanol. Precopolymers can be prepared by adding comonomers, such as triallyl cyanurate, acrylates, vinyl compounds, acrylonitrile, styrene, or diallyl isophthalate. The prepolymers and precopolymers are bulk polymerized by mixing the prepolymer or precopolymer with large amounts of free-radical initiators (benzoyl peroxide, *tert*-butyl perbenzoate) and molding at temperatures up to 200 °C and 40 – 45 bar for about 15 min. Because of their outstanding mechanical and electrical properties, copolymers containing diallyl phthalate are suitable for specialty coating and for embedding, especially in the production of electronic devices. For example, the moisture-sensitive epoxy compounds now used in light-emitting diode (LED) displays can be replaced by stable diallyl phthalate epoxy encapsulating resins [144], [145].

By adding inorganic materials to diallyl phthalate prepolymer compositions, reinforced thermosetting molding compounds can be obtained. Glass cloth or paper can be impregnated with a solution of prepolymer, monomer, and peroxide initiator. After removal of the solvent, the glass cloth or paper is cured to give the desired film-protected material, which is used for decoration, stain-resistant overlays for household articles, and furniture.

Diallyl isophthalate (DAIP) has the advantage over the ortho isomer that it polymerizes faster and gives polymers of better heat resistance. The DAIP prepolymer is less stable than the diallyl phthalate prepolymer. Cured moldings from DAIP monomer-prepolymer compositions can be better processed than cured diallyl phthalate moldings because of their greater fluidity. Compositions containing DAIP prepolymers can be used for the production of hard, translucent, abrasive-resistant, and laser-trimmable coatings [146].

Diallyl esters of aliphatic dicarboxylic acids, e.g., diallyl succinate, adipate, and sebacate, are preferred for the preparation of soluble, thermoplastic precopolymers that sometimes

contain vinyl monomers. These precopolymers can also be used for graft copolymerization with preformed polymers; heat- and solvent-resistant adhesives, plastics, and coatings are produced by this technique.

Diallyl maleate and diallyl fumarate have additional activated double bonds and copolymerize readily with styrenes, vinyl ethers, and acrylates. The less reactive allyl groups remain intact and can subsequently be cross-linked by heating with peroxides or treating with high-energy radiation. As in the case of the saturated diallyl esters, soluble precopolymers are obtained by heating the appropriate mixture of the monomers in the presence of peroxides [147]. Preferential uses are castings and moldings, plastisols, and adhesives.

The allyl acrylic monomer of most importance is allyl methacrylate; allyl acrylate is of secondary importance. Both are used in small amounts for the preparation of soluble, fusible copolymers that can be cross-linked in a subsequent reaction to form insoluble, heat-resistant plastics and coatings. Homopolymers also can be produced by radical-initiated polymerization but are too expensive and are of poorer quality than copolymers. About 10 % of allyl methacrylate and allyl acrylate is copolymerized with other acrylic esters. Preformed vinyl polymers can be cross-linked and processed to form graft polymers. A copolymer of 10 % allyl methacrylate and 90 % vinyl chloride is a flame-retardant additive for polypropylene in amounts of up to 30 % relative to the polyolefin [148]. Allyl acrylate is used in the production of dental plastics, optical lenses, reinforced plastic adhesives, coatings, rubbers, and components in printing processes. It can also be used to modify the properties of cotton [149], [150] or nylon 6 [151].

Triallyl cyanurate is used preferentially as a cross-linking agent in copolymers. On heating it may polymerize violently and then isomerize to the more stable triallyl isocyanurate [*1025-15-6*] with the allyl groups attached to the nitrogen atoms [152], [153].

At 30 °C viscous solutions of prepolymers form slowly. Triallyl cyanurate is used for the production of heat- and solvent-resistant coatings and moldings, reinforced plastics, and adhesives. Addition of 5 – 10 % triallyl cyanurate to polyester – styrene or methyl methacrylate yields cast sheets of improved mechanical and thermal stability. Short-term heating of triallyl cyanurate with polymers in the presence of peroxides at 180 °C gives cross-linking; valuable copolymers are thus obtained from poly(vinyl chloride) elastomers [154] and fluoroelastomers [155]. Ethylene polymers and copolymers also may be cross-linked under similar reaction conditions [156]. High-impact plastics have been obtained by grafting butyl acrylate-triallyl cyanurate copolymer with a styrene – acrylonitrile mixture [157]. Other examples of peroxide-initiated curing with triallyl cyanurate (2 – 5 %) at 150 – 160 °C are polyurethanes [158], nylons [159], cellulose [160], polyoxyethylene [161], vinyl-substituted polysiloxanes [162], and acrylate copolymers [163]. Crosslinking of polycarbonate with triallyl cyanurate by UV irradiation in the presence of polythiols gives scratch-resistant coatings [164].

Triallyl phosphate can explode on heating to about 130 °C and polymerizes rapidly on exposure to air. A possible commercial application of this reactive monomer is the cross-linking with polyolefins in the presence of peroxides and, if necessary, in the presence of foaming agents [165].

3.3.2. Other Uses

Some allyl esters find application as plasticizers, textile auxiliaries, and insecticides. Allyl cinnamate [*1866-31-5*] is a component of perfumes. 2,3-Dibromopropyldiallyl phosphate [*33528-41-5*] has been proposed as a flame retardant in poly(ethylene terephthalate) fibers [166]. Allyl esters also are suitable as diluents for the less reactive peroxides and as dispersion media for pigments and fillers.

4. Allyl Ethers

4.1. Properties and Uses

Simple allyl ethers, such as diallyl ether or alkyl allyl ethers, have only minor commercial importance. Valuable allyl ethers are polyol allyl ethers and allyl ethers that contain an epoxy group.

Allyl glycidyl ether [*106-92-3*], (allyloxymethyl)oxirane, M_r 114.14, *bp* 87.5 – 88 °C (10.9 kPa), d_4^{20} 0.9678, n_D^{20} 1.4345, is a toxic liquid used as an additive for epoxy resins and as a comonomer in polyglycols and polyolefins. Crosslinking is achieved by irradiation or by thermally induced peroxide decomposition. Copolymerization of allyl glycidyl ether with acrylamide or *N,N′*-methylenebis(acrylamide) yields water-soluble polymers containing epoxy groups. These can be condensed with pharmacologically active (controlled-release) compounds to form pharmacologically active polymers [167].

Ethylene glycol diallyl ether [*7529-27-3*], 1,2-bis(allyloxy)ethane, $C_8H_{14}O_2$, M_r 142.20, *bp* 35 – 37 °C (0.13 kPa), d_4^{20} 0.8940, n_D^{20} 1.4340, is polymerized oxidatively with cobalt acetate and air in methanol solution soaked on the surface of filter paper. The resulting polymeric product confers a high degree of hydrophilicity to the filter paper [168].

Partial allyl ethers of trimethylolpropane and pentaerythritol are used to increase the drying rate of alkyd drying-oil coatings. By condensing a mixture of various pentaerythritol allyl ethers with polyesters and ethylene glycol monobutyl ether [*111-76-2*] and then curing with cobalt octanoate, a film of high tensile hardness and flexibility can be obtained [169].

Tetraallyl pentaerythritol ether [*1471-18-7*], $C_{17}H_{28}O_4$, 296.41, *bp* 124 – 125 °C (0.13 kPa), d_4^{20} 0.9497, n_D^{20} 1.4595, can be added to lubricating oil to improve its viscosity index (i.e., to reduce temperature effects) [170].

Allyl Ethers of Carbohydrates. Sucrose polyethers copolymerize with acrylic acid to yield branched, water-soluble polymers. Allyl ethers of starches have been proposed as air-drying protective coatings and as varnishes but have found only limited commercial interest because of their instability and water sensitivity.

4.2. Production

Allyl ethers of low molecular mass, such as diallyl ether and alkyl allyl ethers, are prepared by heating allyl alcohol or mixtures of allyl alcohol with monoalkanols in the presence of mineral acids. The more valuable polymerizable allyl ethers of polyols are prepared by reaction of allyl chloride with the polyols in the presence of sodium hydroxide [171], [172] or by treating an aqueous solution of the polyol with allyl chloride in a two-phase system to which a phase-transfer catalyst has been added. Using tetrabutylammonium bromide [*1643-19-2*] as the phase-transfer catalyst, up to 99.7 % tetraallyl pentaerythritol ether is obtained from the reactants [170].

5. Allylamines

5.1. Properties and Uses

Allylamine [*107-11-9*], $CH_2{=}CHCH_2NH_2$, C_3H_7N, M_r 57.10, *bp* 54.5 °C, d_4^{20} 0.7621, is a liquid with an ammoniacal odor. It can be converted to *N*-allylamides or -imides by reaction with esters, acid anhydrides, or acid chlorides. Allylamine is oxidized at 400 °C on a bismuth molybdate catalyst; acrylonitrile and propionitrile are the main products (85 % combined yield) [173]. Plasma polymerization of allylamine gives polymers that can be used as reverseosmosis membranes. A possible future application of these membranes is in closed environmental systems, such as manned spacecraft [174], [175]. Allylamine is useful as a corrosion inhibitor when pickling steel in acid [176]. The rhodium-catalyzed reaction of allylamine with carbon monoxide at 120 °C and 10 MPa yields 67 % γ-butyrolactam [*616-45-5*] [177].

Diallylamine [*124-02-7*], $C_6H_{11}N$, M_r 97.16, *bp* 111 – 112 °C, can be cyclized to give substituted pyridines [178]. It is an intermediate in the production of pharmaceuticals and resins.

Triallylamine [*102-70-5*], $C_9H_{15}N$, M_r 137.23, *bp* 150 – 151 °C, has been proposed as a catalyst for the production of polyesters [179] and as an initiator for the polymerization of butadiene [180].

Methallylamine [*2878-14-0*], $CH_2{=}C(CH_3)$-CH_2NH_2, C_4H_9N, M_r 71.12, *bp* 78.8 °C, d_4^{20} 0.782, is dehydrogenated to methacrylonitrile

[*126-98-7*] over a silver catalyst. Copolymerization of methallylamine with acrylonitrile increases the affinity of polyacrylonitrile fibers for dyes [181].

5.2. Production

Allyl chloride reacts with aqueous ammonia at about 100 °C to give a mixture of the hydrochlorides of allyl-, diallyl-, and triallylamine, from which the pure amines are obtained by distillation [182]. Methallylamine is produced in a similar manner [183].

Table 5. Hepatotoxic effect ∗ of some allyl and propyl compounds in rats [190]

	Dosage, mg/kg	Degree of liver necrosis
Allyl alcohol	25	1.5
Allyl formate	40	2
Allyl acetate	45	2.5
Allyl butyrate	85	1.5
Allyl caproate	75	2.5
Allyl heptanoate	165	3
1-Propanol	2160	0
Propyl formate	1330	0
Propyl acetate	3120	0
Propyl butyrate	5000	0

∗ Degree of macroscopically visible liver necrosis on day 5 after oral application of 1/3 of the LD_{50} for four consecutive days. Degree 1: just clearly visible; degree 3: severe necrosis.

Pure allylamine can be prepared by hydrolysis of allyl isothiocyanate [184], thermal cleavage of allyl dithiocarbamate [185], hydrolysis of diallyl cyanamide [186], or ammonolysis of triallylamine [187]. Allylamine may be produced also by electroreduction of acrylonitrile on lead cathodes [188]. Polyallylamines are readily obtainable by catalytic hydrogenation of poly(acrylonitrile) over a Raney nickel catalyst [189].

6. Toxicology and Occupational Health

Allyl compounds are stronger irritants to the skin and mucous membranes and are more toxic than the corresponding alkyl compounds (Table 5). Many allyl compounds are absorbed easily through the skin and mucous membranes. After absorption, aliphatic allyl compounds can cause severe liver damage, in contrast to comparable alkyl compounds (Table 5). Other target organs are mainly the central nervous system, the kidneys, and the hematopoietic system.

Allyl Chloride [*107-05-1*]**.**

Acute and Subacute Toxicity. LD_{50} = 460 mg/kg (rat, oral) [191]; LD_{50} = 3.7 mg/kg (rabbit, percutaneous) [5]; LC_{50} = 11 mg/L (rat, inhalation, 2 h) [191]. The inhalation of 3 ppm allyl chloride during 7 h/d on 5 days a week was tolerated by a group of rats, guinea pigs, and rabbits for 180 days without irreversible damage occurring. An analogous test using 8 ppm over a period of 35 days led to damage of the liver and kidneys [192]. Further experiments demonstrate a neurotoxic effect of allyl chloride, in particular to the peripheral nerves of cats and rabbits [191], [193], [194].

Carcinogenicity, Mutagenicity, Embryotoxicity. So far, little information on the *carcinogenic activity* of allyl chloride is available [195–199]. A carcinogenic effect is suspected, although a definite statement cannot be made at present [195]. The *mutagenicity* of allyl chloride has been confirmed in various tests [200–203]. A toxic effect on the development of rat embryos, as well as increased *embryo mortality,* was established in rats that had inhaled air containing allyl chloride at a concentration of 3.1 mg/m^3. At 0.29 mg/m^3 no negative effects occurred [204].

General Characteristic Effects. Allyl chloride causes strong irritation of the skin and the mucous membranes. It is absorbed by inhalation, by ingestion, and through the skin. Direct contact and exposure to air – allyl chloride mixtures lead to strong irritation of the eyes, mucous membranes, and nasopharyngeal cavity. Acute symptoms are numbness, unconciousness, and – particularly upon repeated and lengthy exposure to higher concentrations – pulmonary edema. The heart and circulatory system, liver, and kidneys are endangered. At longer exposure times and higher concentrations, fatal poisoning is possible. After prolonged exposure, chronic damage of the liver and kidneys occurs [5], [205], [206].

Occupational Health. Because of its toxicity, allyl chloride is classified as a poisonous material. The threshold limit value (TLV) and the MAK are 1 ppm (8 h time weighted aver-

age) [207–209]. The short-term exposure limit is twice as high: 2 ppm [205], [208]. Because of its suspected carcinogenic potential, allyl chloride is classified in group III B by the MAK commission [207]. In the former USSR, the maximum allowed workroom concentration is set at 0.1 ppm [210].

The particularly pungent odor of allyl chloride cannot serve as an adequate warning signal. The odor perception thresholds, at which 50 and 100 % of exposed persons perceive allyl chloride vapors in the air, are 3 to 6 and 25 ppm, respectively [5]. These values are considerably above the permissible working concentrations.

So far, few investigations in occupational medicine on the effects of allyl chloride exist [193], [205], [211].

Allyl Alcohol [*107-18-6*]**.** With respect to its irritating and toxic effects, allyl alcohol is the best investigated aliphatic allyl compound. The odor perception threshold is approximately 0.8 ppm [212], and 6 – 12 ppm causes irritation of the nose. At a concentration of 25 ppm, severe irritation of the eye occurs, with lacrimation, photophobia, blurred vision, and retrobulbar pain [212]. Corneal necrosis results in temporary blindness in persons exposed to higher concentrations [213]. Sensitive persons may react with slight irritation of the eyes at concentrations of 2 – 5 ppm [214], [215]. In animal experiments daily inhalation of concentrations between 2 and 7 ppm (7 h/d) has been tolerated without irritation in dogs, rabbits, guinea pigs, and rats during periods of up to 6 months [192].

The threshold limit value (TLV) and the MAK value are 2 ppm [208], [209]. The short-term exposure limit is twice as high, namely 4 ppm.

A single oral application of allyl alcohol (0.02 mL/kg) caused liver necrosis in rats and the death of 7 out of 12 animals [216]. The oral and cutaneous LD_{50} for rabbits is 50 – 80 mg/kg, and for rats 64 mg/kg [217], [218]. A single dermal application of allyl alcohol to dogs (approximately 0.2 mL/kg) caused lethal gastrointestinal hemorrhages within a few hours [217]. In rats hepatotoxic effects with liver cell necrosis were observed after a single application of 62.5 µL/kg by gavage [219] and after a single intraperitoneal injection of 0.5 mL/kg [220]. On the other hand, the daily application of 50 ppm of allyl alcohol (4.8 – 6.2 mg/kg) with the drinking water was tolerated by rats for 15 weeks without effect [221]. In cases of skin contamination, the danger of systemic intoxication brought on by the high absorption rate of allyl alcohol through the skin (one drop of allyl alcohol equals approximately 50 mg) exists in addition to local irritation [218].

Allyl Esters. The toxicological effects of allyl esters are quite similar to those of allyl alcohol. Local irritation and damage to the central nervous system and the liver caused by absorption are the main effects. For *allyl acetate* [*591-87-7*], the dermal LD_{50} in rabbits is 1000 mg/kg and the LC_{50} in rats is 1000 ppm after 1 h of inhalation. Comparable values are reported for *diallyl maleate* [*999-21-3*] [212]. Table 5 shows the hepatotoxicity of simple allyl esters, compared with some propyl esters. The hepatotoxicity of *diallyl phthalate* [*131-17-9*] is probably in the same range as that of others in the table, but it causes only slight irritation of the skin or mucous membranes [222]. *Allyl methacrylate* [*96-05-9*] has an oral LD_{50} in rats of 430 mg/kg and the dermal LD_{50} in rabbits is 500 mg/kg. Allyl methacrylate is easily absorbed through the skin. The inhalational LCLo (lowest lethal concentration) in rats has been found to be 500 ppm [223].

Allyl Ethers.

Allyl glycidyl ether [*106-92-3*] has an LD_{50} of 390 mg/kg (mouse, oral) and an LD_{50} of 1600 mg/kg (rat, oral). In rabbits, the dermal LD_{50} is 2550 mg/kg. Inhalational toxicity has been estimated: LC_{50} = 270 ppm (mice, 4 h) and 670 ppm (rats, 8 h) [224], [225].

Allyl glycidyl ether causes only slight irritation of the skin but is strongly irritating and corrosive to the eye. Following inhalation, the irritation of the respiratory tract can lead to pulmonary edema or to secondary bronchopneumonia [224], [225]. After absorption, systemic intoxication with disorders of the central nervous system and morphologic damage to the liver, kidneys, and spleen can occur [224], [225]. In humans, dermal sensitization has been observed besides the irritating effects [224], [225]. The threshold limit (TLV) and the MAK values are 10 ppm or 45 mg/m^3 [208], [209].

Diallyl ether [*557-40-4*] smells like horseradish and severely irritates the mucous membranes; the LD_{50} is approximately 270 mg/kg (rat, oral) [226]. Diallyl ether is absorbed easily through the skin; the LD_{50} is 540 mg/kg (rabbits, dermal, estimate) [226].

Ethylene glycol diallyl ether [*7529-27-3*] has an oral LD_{50} in rats of 1020 mg/kg. Exposure to it for 24 h causes severe irritation of the skin (500 mg) and eyes (250 µg) of rabbits [227].

Allyl ethyl ether [*557-31-3*] and *allyl vinyl ether* [*3917-15-5*] are irritants to the skin, mucous membranes, and eyes [228]. For allyl vinyl ether, the oral LD_{50} in rats is 450 mg/kg [228].

Allylamines. Allylamines also are irritating to the skin and mucous membranes and are corrosive to the eye. In general, allylamines are absorbed easily through the skin. The dermal LD_{50} of *allylamine* [*107-11-9*] in the rabbit is 35 mg/kg [229]. The oral LD_{50} has been determined to be 106 mg/kg (rat) and 57 mg/kg (mouse) [229], [230]. For rats, the inhalational LC_{50} is 286 ppm (4 h). In humans, the odor perception threshold of allylamine is approximately 2.5 ppm, whereas the TCLo (lowest toxic concentration) has been found to be 5 ppm (5 min). Above 2.5 ppm, irritating effects on the respiratory tract can occur; 14 ppm is intolerable [231].

In contrast to other allyl compounds, allylamine, diallylamine [*124-02-7*], and triallylamine [*102-70-5*] can cause myocardial degeneration as well as damage to the kidneys and liver. This has been observed in rats and rabbits [230]. Allylamines cause a severe primary fibrosis of the myocardium [232], [233]. The oral application of allylamine in the drinking water over 81 – 104 days caused a dose-dependent myocardial degeneration in rats [233].

Alumina → Aluminum Oxide

Aluminothermic Processes

In this keyword, only the general aspects of aluminothermic processes are discussed: The technical production of the individual metals and alloys is described in the corresponding keywords, e.g.: ferroboron → Boron and Boron Alloys; chromium and ferrochromium → Chromium and Chromium Alloys; ferromolybdenum → Molybdenum and Molybdenum Compounds; ferroniobium → Niobium and Niobium Compounds; ferrotitanium → Titanium and Titanium Alloys; ferrotungsten → Tungsten, Tungsten Alloys, and Tungsten Compounds; ferrovanadium → Vanadium and Vanadium Compounds

1. Introduction

The usual method of reduction by carbon is inapplicable to the reduction of refractory oxides and ores. The products commonly covered under this title are usually required to be low in carbon and they are avid carbide formers. Also, no conventional refractories would stand up to the long reduction times at the high temperatures required. For such products, advantage is taken of the high temperatures achieved and the rapidity of metallothermic reactions using reactive metals, notably Al.

Early examples of such reactions are BERZELIUS' reduction of K_2TaF_7 by Na and WÖHLER's reduction of $AlCl_3$ by Na, in 1825 and 1828, respectively. However, the father of aluminothermic processes was undoubtedly GOLDSCHMIDT who, in 1898, described the production of low-carbon, high-melting-point metals, without extraneous heat, by feeding an exothermic mix into an already ignited first portion [1].

The term "aluminothermic processes" can cover a wide field. For the present purposes it is taken, as is generally understood, to be the manufacture, by Al reduction of refractory oxides or ores, of metals and alloys mainly used in the steel and superalloy industries. Because some important alloys are produced aluminosilicothermically side by side with those produced aluminothermically, they are included in the survey.

The main alloys and metals under discussion are Cr metal [*7440-47-3*], FeB [*11108-67-1*], FeMo [*11121-95-2*], FeNb [*11108-69-3*], FeTi [*12719-90-3*], FeV [*12604-58-9*] and FeW [*12604-57-8*]. There are many minor variations, such as CrC, where superior purity or the absence of Fe is required for alloys used in superalloy production, and FeNb from Nb_2O_5 instead of ore, where extra purity is required, again for superalloys.

Aluminothermic Mn [*7439-96-5*], formerly of importance, has been superseded by electrolytic Mn, and aluminothermic production of FeTi has largely given way to induction furnace melting of Fe and Ti scraps. The latter method also now substitutes for the former, dangerous, highly exothermic production of 55 – 60 % TiAl and 55 – 60 % ZrAl. When possible, combined electroaluminothermic methods can be used.

Because most basic reactions require extra heat this is provided by Al and a vigorous oxidant. Aluminum is an expensive fuel. At an Al

10.1002/14356007.a01_447

powder price of 1400 $/t and a small-scale electricity cost of 4.9 C/kW h the heating effect of Al combustion costs about three times that of electricity.

Although a minor proportion of production, some FeB, FeNb, FeTi, and FeV is produced in the arc furnace. In view of the small tonnages involved, such productions usually occur only where an arc furnace exists for other purposes.

Apart from the necessity of metallothermic reduction advantages of the process as compared to conventional reduction processes are:

- Very rapid reaction with less heat loss by radiation and convection
- Much less gas volume
- Easy accomodation of diverse productions
- Small plant investment (important, considering the small production).

A disadvantage of metallothermic production is that no refining of the metal is possible. It is important to leave the slag in situ to allow metal drops to settle into the regulus, so that one is faced with a large depth of slag quickly crusting over. Alternatively, if the slag is tapped, requiring subsequent ore dressing processes to recover included metal, the metal regulus quickly becomes sluggish. Therefore, the composition of the mix must be regulated very carefully to produce the optimum combination of oxygen and reactant metal levels in the product, and all ingredients must be low in harmful impurities. Obvious ones are C, S, and P. Other impurities in the various ores used for different products are As, Sn, Pb, Sb, and Cu. Nitrogen is not usually a problem because the metal regulus formed is protected by the slag layer. Chromium metal, used in superalloys and electric heating elements, is an extreme case, where, apart from low impurities generally, certain impurities, such as Ga, Pb, and B, must be kept down to a few parts per million.

The worldwide – excluding the former USSR and China – production of metal and alloys by aluminothermic processes is shown in Table 1.

Table 1. Production of metal and alloys by aluminothermic processes

	t/a	Expressed as
Cr	4550	Cr
FeB	1350	18 % B
FeMo ∗	40500	65 % Mo
FeNb	16300	65 % Nb
FeV	25000	80 % V
FeW	4000	80 % W

∗ The FeMo represents about one third of the total Mo used in the steel industry; the remaining two thirds are used as MoO_3.

2. Basic Metallurgy

A metallothermic reduction of a metal compound is possible when the reductant metal has a greater affinity for the nonmetal element of the compound than the desired metal. In various branches of metallurgy the nonmetal may be a halide, sulfur, or oxygen. The reductant metal is usually Al, Si, Mg, Ca, or Na. For instance, Ti metal is produced by reduction of halides with Na or Mg and V metal by reduction of V_2O_5 with Ca in a bomb reaction (to prevent vaporization of the Ca). Interesting examples are the reduction of NiO and MoO_3 by Fe in the arc furnace. Aluminothermic processes, as previously defined, depend upon the high affinity of Al for oxygen as compared to that of many other metals, an example being:

$$Cr_2O_3 + 2\,Al \rightarrow 2\,Cr + Al_2O_3$$

2.1. Basic Thermochemistry

Aluminum has a high affinity for oxygen, and the ease of reduction of a metal oxide depends on the difference in oxygen affinity of Al and the metal. The affinity for oxygen is indicated by its heat of formation, ΔH, expressed for comparison purposes as ΔH per mol/oxygen (kJ/mol O). Table 2 gives a selection of ΔH values at the standard temperature of 298 K.

Table 2. Heats of formation of oxides [2]

Oxide	$-\Delta H_{298}$, J/mol oxide	$-\Delta H_{298}$, kJ/mol O
CaO	634.7	634.7
MgO	601.7	601.7
Al_2O_3	1678.5	559.4
ZrO_2	1101.5	550.6
TiO_2	945.4	472.7
SiO_2	911.0	455.5
B_2O_3	1272.8	424.1
Na_2O	415.3	415.3
Ta_2O_5	2047.3	409.5
Nb_2O_5	1900.8	380.2
Cr_2O_3	1130.4	376.8
V_2O_5	1551.6	310.2
WO_3	843.2	280.9
Fe_3O_4	1117.5	279.3
Fe_2O_3	821.9	273.8
FeO	264.6	264.6
MoO_3	745.7	248.7

Figure 1. Change in free energy of oxide formation reactions [3]

A quantitative measure for the stability of an oxide is the Gibbs free energy of formation, ΔG, which is related to the heat of formation by the formula:

$$\Delta G_T^0 = \Delta H - T\Delta S$$

where S is the entropy and is always zero or positive because it corresponds with the increasing atomic disorder of the system with temperature. Figure 1 shows the free energy of formation of the oxides of interest at high temperatures. All oxides become less stable as temperature increases. The more negative the free energy of formation at a given temperature the greater the tendency for that metal to reduce an oxide of less negative free energy.

The free energies of reaction of oxides with Al and Si are given in Figures 2 and 3.

Figure 2. Change in free energy of reaction in the reduction of oxides by aluminum

Although the free energy of reaction is a quantitative measure, not all data necessary for such complex reactions as commercial metallothermic reactions are readily available and it is usual for the practicing metallurgist to rely on heats of formation for calculation of heats of reaction.

Figure 3. Change in free energy of reaction in the reduction of oxides by silicon

2.2. Fundamental Reactions

Although Ca and Mg may be the most suitable reactants, they are not used in the reductions under review. Their basic costs are high compared to Al and Si and 16 parts by weight O require 40 parts Ca, 24 parts Mg, 18 parts Al, or 14 parts Si. Furthermore, the boiling points of Ca and Mg are 1 484 °C and 1 090 °C, respectively. The heats of reaction of the oxides of interest with Al and Si are given in Table 3.

Table 3. Heats of reaction per mole reductant

	$-\Delta H_{298}$, kJ
3/4 TiO_2 + Al → 3/4 Ti + 1/2 Al_2O_3	130.2
3/4 SiO_2 + Al → 3/4 Si + 1/2 Al_2O_3	156.0
1/2 B_2O_3 + Al → B + 1/2 Al_2O_3	202.6
3/10 Nb_2O_5 + Al → 3/5 Nb + 1/2 Al_2O_3	268.8
1/2 Cr_2O_3 + Al → Cr + 1/2 Al_2O_3	273.8
3/10 V_2O_5 + Al → 3/5 V + 1/2 Al_2O_3	373.9
1/1 Wo_3 + Al → 1/2 W + 1/2 Al_2O_3	417.4
3/8 Fe_3O_4 + Al → 9/8 Fe + 1/2 Al_2O_3	420.2
1/2 Fe_2O_3 + Al → Fe + 1/2 Al_2O_3	428.3
3/2 FeO + Al → 3/2 Fe + 1/2 Al_2O_3	442.1
1/2 MoO_3 + Al → 1/2Mo + 1/2 Al_2O_3	466.4
2/3 WO_3 + Si → 2/3 W + SiO_2	348.8
1/2 Fe_3O_4 + Si → 2/3 Fe + SiO_2	352.1
2/3 Fe_2O_3 + Si → 4/3 Fe + SiO_2	363.0
2 FeO + Si → 2 Fe + SiO_2	381.8
2/3 MoO_3 + Si → 2/3 Mo + SiO_2	414.1

A guide for a successful aluminothermic reaction, permitting adequate separation of metal and slag, is a $-\Delta H_{298}$ higher than 300 kJ/mol [4]. This is confirmed in practice: additional heat is required for Cr production, whereas the reaction producing 80 % FeV is so vigorous that it requires cooling. This guide does not apply to silicothermic reactions.

2.3. Auxiliary Reactions

Many reactions require additional heat to produce fully liquid metal and slag. Except for producing pure Cr, the first step is to make an addition of iron oxide plus reactant, giving a higher average heat of reaction. This also has the advantage of producing significantly lower melting points (Table 4).

Table 4. Melting points of some metals (in °C) and of alloys of these metal with iron

V	1 902	80 % FeV	1 770
B	2 180	16 % FeB	1 550
Nb	2 468	65 % FeNb	1 560
Mo	2 620	65 % FeMo	1 900
W	3 410	80 % FeW	2 500

In silicothermic reactions, a proportion of Al is usually used to increase the exothermicity particularly, because the products, e.g., FeW and FeMo, have such high melting points.

Because the alloy specifications have become traditional, although not necessarily ideal, there is a limit to the amount of iron oxide and Al to be added, and, indeed, it may be more economical to increase the heat content of the mixture furhter, by using highly oxidic compounds plus Al. The reactions and the heats of reaction (in kJ/mol Al) for the additives most commonly used are:

$$K_2Cr_2O_7 + 4\,Al \rightarrow 2\,Cr + 2\,Al_2O_3 + K_2O$$
$$\Delta H_{298} = -\,422.0\,\text{kJ/mol Al}$$

$$3\,BaO_2 + 2\,Al \rightarrow 3\,BaO \cdot Al_2O_3$$
$$\Delta H_{298} = -\,812.0\,\text{kJ/mol Al}$$

$$NaClO_3 + 2\,Al \rightarrow Al_2O_3 + NaCl$$
$$\Delta H_{298} = -\,869.2\,\text{kJ/mol Al}$$

$$3\,KClO_4 + 8\,Al \rightarrow 4\,Al_2O_3 + 3\,KCl$$
$$\Delta H_{298} = -\,839.0\,\text{kJ/mol Al}$$

Figure 4. Melting point curves of binary alumina slags

In some cases additional heat was applied formerly extraneously by preheating the charge. This has been given up because of practical difficulties of heating a mixture of low heat conductivity and the danger of premature ignition, with loss of the charge and damage to the preheating equipment. The cheap nitrates are not used now because products low in nitrogen are required and the metals in question are avid nitride formers. BaO_2 is useful because it not only acts as an oxidant, but is a strong base and assists the progress of the reaction by combining with the Al_2O_3 produced. However, its high molecular mass and its one available oxygen atom make it a very expensive oxidant, and its use is confined to highly exothermic mixes, e.g., for TiAl and ZrAl, where it helps to smooth the reaction. The common oxidant is $NaClO_3$, but $KClO_4$ is to be preferred because it is more stable and $NaClO_3$ is hygroscopic. In Cr mixes, $K_2Cr_2O_7$ is used and is preferred to CrO_3 on health grounds as well as expense.

2.4. Fluxes

Both Al_2O_3 and SiO_2 have high melting points, 2050 °C and 1722 °C, respectively. The aim in metallothermic reactions is to produce a fluid slag, so as to permit good separation of slag and metal. In the case of aluminosilico reactions, residual iron oxide and Al_2O_3 are already good fluxes, and lime also is used because the strongly basic CaO, apart from fluxing, lowers the activity of Al_2O_3 and SiO_2.

In aluminothermic reactions residual oxides may play a part, the compound $Al_2O_3 \cdot TiO_2$ having a melting point of 1590 °C; Na_2O and K_2O, not completely vaporized, also assist. The usual flux is CaO which has a pronounced effect on the melting point of Al_2O_3. It is not used in Cr manufacture as it spoils the slag for use in refractories and calcium chromite is a stable compound.

Figure 4 shows the effect on melting point of additions of several oxides to Al_2O_3.

The energy required to fuse the flux is partially compensated by the heats of formation of the compound oxide (Table 5).

Table 5. Heats of formation of compound oxides

Compound	$-\Delta H_{298}$, kJ/mol
$Al_2O_3 \cdot SiO_2$	192.6
$2Al_2O_3 \cdot B_2O_3$	69.5
$BaO \cdot Al_2O_3$	100.5
$CaO \cdot Al_2O_3$	15.1
$CaO \cdot SiO_2$	89.2

2.5. Formation of Intermetallic Compounds

The heat of reaction of the mixture can be increased by the formation of intermetallic compounds. Table 6 gives some examples. However, this is restricted in that most of the higher heats of formation belong to unwanted compounds because the usual aim is to keep residual elements, such as Al and Si, to a minimum. Of the alloys considered it is only in the case of FeTi and to a lesser extent in that of FeB that aluminides have some significance.

Table 6. Heats of formation of intermetallic compounds

Compound	ΔH_{298}, kJ/mol
FeTi	40.6
FeB	29.3
$FeAl_3$	112.2
FeSi	77.0
TiAl	80.8
CaSi	150.7
AlB	67.0

All reactions are equilibria. Commercial alloys must be low in oxygen and most alloys can be produced at 1 % Al or Si without appreciable oxygen content. This is not the case with FeTi, where the equilibrium cannot be driven further than Al levels of 4 – 6 %.

2.6. Thermochemistry in Practice

A commercial metallothermic reaction must provide sufficient heat to drive the reaction as far to the right side of the equation as possible, plus that heat required to bring the products to a temperature sufficiently high to permit separation of metal and slag and to provide for heat losses. The amount of total heat must be the minimum required, because heat is expensive and because excess heat supplied to an exothermic reaction moves the equilibrium in the undesired direction.

Heats of formation have not always been determined at the high operating temperatures. Working on heats of formation at 298 K requires knowing the specific heats, latent heats, and, in charges employing sodium salts and chlorates, the heats of vaporization. Slags can be complex so that little idea can be had of their heats of formation. The amount of heat losses cannot be forecast and varies with the size of charge. Losses can be established and compensated for only by trial and error.

Therefore, available information is used as much as possible, accompanied by intelligent extrapolations of such information. Final adjustments to the charge are a matter of trial and error.

A very simple example is:

$$Cr_2O_3 + 2\,Al \rightarrow 2\,Cr + Al_2O_3 \quad \Delta H_{298} = -548\,kJ$$

Heat required for products at 2000 °C:

Al_2O_3	$H_{2273} - H_{298}$	356 kJ
2 Cr	$H_{2273} - H_{298}$	184 kJ
amounts to:		540 kJ

According to this, there is a heat balance, so there should be a satisfactory result. However, it is found in practice that 125 kJ extra heat are required, provided by Al plus $K_2Cr_2O_7$ and/or $KClO_4$. This 125 kJ (for a certain size of charge) is a measure of the heat losses. More would be required for small charges and less for bigger charges. It is interesting that this conforms with the guide.

Chemical composition of ores is some guide to improving the heat balance. Generally the higher the state of the oxide in the ore, the higher the heat of reaction with Al or Si. A classical example was that of Mn ore where the reaction $3\,MnO + 2\,Al \rightarrow 3\,Mn + Al_2O_3$ did not supply sufficient heat. A preoxidation to Mn_3O_4 produced a satisfactory result. Preoxidation also is found beneficial to some ilmenites.

There are many other factors affecting the fine control of an exothermic reaction, and it is not always economic to indulge in laboratory control of all of them. They mainly affect the speed of the reaction, which should be an optimum to minimize heat losses but not to create excess heat with its adverse effect on the equilibrium.

Granulometry. If the charge is to be reacted in bulk then the ideal would be a charge of concrete-type granulometry, giving maximum contact and minimum air inclusion. However, to provide effective heat control, charges usually are fed. There should be an optimum particle size of the ingredients, therefore, coarse enough to minimize dust losses but fine enough to give an adequate speed of reaction. Aluminum powder can be controlled, because suppliers will supply within reasonable size ranges. In some cases, such as the highly exothermic FeV reaction, Al pellets and turnings can be used and they are used also to some extent in the very competitive production of the cheap alloy FeTi. These are crude raw materials and different parcels require slight adjustments to the mix. Ores are a different matter. These must usually be used as they arise; the coarser they are in any one production, the more the amount of heat required. Where ores are extremely fine, leading to high dust losses, it may be economical to pelletize.

Mineralogic Structure of Ores. Complex ores, such as pyrochlore, can vary widely in structure, and different parcels require adjustments to the mix.

Bulk Density. This is related to granulometry, but even in Cr_2O_3, which would be expected to be uniform from parcel to parcel and where grain sizes are of a few microns, variations in

the supplier's final calcination temperature can affect the bulk density greatly and hence the recovery.

Mass of Charge. The percentage of heat losses varies inversely with the size of charge. These losses cannot be measured, but when the mass of a charge is increased, less heat per unit charge is required; this decrease can be obtained by an intelligent estimate finalized by trial and error.

Rate of Feeding. This is very much an art and efficient feeding can minimize some of the above mentioned difficulties. The general aim is to maintain a cover of unreacted mix on the surface of the liquid slag, so as to minimize radiation losses but not to feed too fast and produce too hot a reaction.

It can be seen from the above that whereas thermochemistry plays a vital role in providing the basic knowledge for any metallothermic production, there are other "fine tuning" adjustments that are a matter of experience.

3. Commercial Production

There are two methods of promoting the reaction. One is to fill the reaction vessel with the charge and ignite it via an easily ignitable mixture, such as BaO_2 or Na_2O_2 plus aluminum; the reaction then proceeds from top to bottom of the charge. This is a wasteful method because only approximately one third of the capacity of the reaction vessel is used. The mix calculation must be very accurate because no control of the speed of reaction can be exercised. Because the charge is always covered by liquid slag, dust losses should be low, but there can be considerable loss by splashing owing to the violence of the reaction. The short reaction time should mean low heat losses, but this advantage is counteracted by the intense radiation from an always liquid surface. This method is seldom used, but there are some reactions that are so exothermic that they are dangerous and practically impossible to feed, such as those for the minor products 55 – 60 % TiAl and ZrAl. This "firing down" method is used sometimes also for FeW production, where the extra heat supplied to achieve the high melting point requires a highly exothermic reaction near the limit of feedability.

The second method, almost universal, is to use a charge slightly more exothermic than that for "firing down," to ignite a small portion in the reaction vessel, and to feed the remaining charge. By doing so, the full capacity of the vessel is used so that vessel preparation costs per unit production are approx. one third those of the "firing-down" method. Another great advantage is that the speed of the reaction can be controlled by varying the feeding rate so that it gets neither too hot nor too cold. As mentioned previously, this is quite an art, but it is surprising how soon a skilled worker becomes used to visual control of the temperature of the reaction.

There are also two types of reaction vessel. One is a mobile steel pot, lined with refractory. The other is a sand bed into which cylindrical holes are dug and lined with firebrick. This latter method usually is confined to aluminosilico reactions, such as those for FeW and FeMo.

Pot reactions are carried out in firing chambers, where the under pressure, as compared to that outside, is kept to the minimum required for complete exhaust of fume consistent with the charge feeder's need to observe the reaction but to keep dust losses to a minimum. *Sand bed reactions* are usually under a movable hood connected to the main flue. Whereas tall chimneys were once the solution to disposal of fume, modern conceptions of pollution control demand efficient dust collection. Owing to the volatility of MoO_3, this production demands its separate dust collector, the recovery from which makes the difference between profit and loss on the operation. For other productions, because of the small tonnage of individual products and because the fume is largely Al_2O_3, CaO, NaOH, etc., with low contents of valuable oxide, a communal collector is used. Collectors are of many types, but the most efficient is the reverse-jet filter. Because of the presence of CaO, NaOH, etc., the filter, when not in use, must always be kept above 100 °C to prevent caking of the fume on the bags.

Figure 5 shows the arrangement, in principle, for feeding, reaction in a chamber, and fume extraction. After firing, the reaction pots must be left to cool to allow final settling out of metal droplets and eventual solidification. Depending on the size of the reaction, solidification can take

a long time, but 24 h, which often fits in with the overall routine of the production, is usually sufficient. The pot is then stripped, leaving a block of metal with adherent block of slag. The whole is then carefully quenched in a water tank, which causes the slag block to separate and embrittles the metal to some extent, facilitating subsequent crushing.

Figure 5. Reaction chamber with feeding hopper, reaction vessel, and dust collector
a) Feeding hopper; b) Feed-regulating valve; c) Feeding chute; d) Separable refractory-lined steel plate cylinder; e) Refractory-lined base; f) Optional magnesite inner lining; g) Firebrick-lined chamber; h) Filter; i) Offtake to chimney

The sides of the metal block are surrounded by an adherent mixture of metal and slag created by penetration into the refractory lining. This easily breaks away and is consumed in the next reaction. The top surface, containing pockets of very adherent slag, requires removal by automatic hammers and, in the last resort, by hand chipping hammers. The bottom of the block usually requires less attention. Final cleaning of the whole block is by shot blasting.

The block is coarsely broken up by a mobile hammer of the pile driver type and crushed to desired size in jaw crushers and/or rotary crushers with intermediate screenings. There is immense variety in customer's size requirements, ranging from, say, 15-cm lumps for bulk users down to graded powders for welding rod manufacturers. An increasing demand is for bags of 6 mm and down alloy, each containing a fixed weight of the desired alloying element.

3.1. Pot Design and Construction

Although there is theoretically no limit to the size of the charge, as compared to steel production, the weights are small for the following reasons:

Costs. Overall, raw materials are expensive. It is the aim of a producer to try to keep pace evenly with sales, holding modest stocks of raw materials and finished product. The total annual production of any one producer is small and diverse, with, in some cases, several specifications for one product.
Handling Facilities. The total weight of a refractory-lined pot full of metal and slag is about three times that of the metal produced. Crane size is limited by cost and the small building required for carrying out the reactions, and for total operation lift trucks are convenient.
Preliminary Metal Breaking. The small tonnages involved preclude a very expensive, large, preliminary breaking plant. Some alloys, particularly FeMo, are very tough and metal block thickness is usually limited to 30 – 35 cm.
Metal Specification. Some residual specifications are very tight, notably that for Al in Cr metal. A mishap in the weighing of the charge can produce an off-grade block that may be in stock for a long time.
Refractory Failure. Although rare, there can be an occasional failure of the refractory, producing breakout of metal and slag at high economic loss.

Therefore, metal block weights usually vary between 1000 and 2500 kg and, depending on the density of metal and slag, two pot sizes suffice. A small pot of ca. 200 kg metal capacity is useful for intermediate size investigations on new raw materials. A typical pot covering 1000 – 1750 kg metal would have internal dimensions of ca. 100 cm diameter and 125 cm height and one for 2500 kg would have the same height but be of 120 cm diameter in order to avoid too thick a metal block.

The outer construction consists of a plate steel cylinder attached to a heavy steel base by quick-acting lugs. The base may be on wheels or adapted for lift truck operation. The lining

is of moistened, crushed slag from chromium or ferrovanadium production, because this is a reasonably pure corundum. To ease cleaning of the metal block, magnesite tiles may be used in the metal zone, particularly for the hotter reactions. After preparation of the refractory base, either from bricks or ramming of crushed slag, the sides are rammed around a tapered, withdrawable template. Ramming is by hand, by pneumatic or electric hammer, or by jolting on a foundy jolt molding machine. The lining must then be dried for several hours to remove moisture. It is taken up to a dull red heat.

Basic sand bed operation is to construct a well in the sand bed from unmortared firebricks which takes the whole molten charge. After sufficient time is allowed for metal to settle out, a channel is made through the sand at the slag-metal interface level and the slap tapped off. A variation is to use a similar well in the sand bed sufficient to accomodate only the metal, topped by a firebrick-lined steel shell to accommodate the slag, with ample sand seal at the junction. After the reaction, the slag is tapped at the junction and the shell used several times.

3.2. Charge and Charge Preparation

Ideally, there would be an optimum size for raw materials, fine enough for a successful reaction but as coarse as possible to minimize dust losses. Fortunately, most oxides and ores are of reasonable size in these respects. Wolfram ores may have to be ground sometimes and it is known that very fine ores, such as pyrochlore, have been pelletized. Chromium oxide, at a grain size of a few µm, can be expected to give high dust losses but the grains have a strong tendency to self-adherence so that the particles are much larger. Even so, there is a slightly noticeable difference in recovery when different oxides are used, this varying directly with the final calcining of the oxide during its manufacture. The calcination increases grain size and density.

Auxiliary oxidants are of satisfactory grain size with the proviso that $NaClO_3$ tends to agglomerate on storage and must be sieved down to max. 1 mm before use.

The minimum size of Al is limited by dust losses and the risk of dust explosions. It should not be below ca. BSS 240 = 64 µm. The size used in exothermic reactions then depends on the reaction. For chromium it is on the order of average 0.25 mm, for FeB and FeNb, 0.45 mm, and the Al powder can be partially substituted by cheaper foil powder. In the highly exothermic FeV reaction, where the V_2O_5 is in the form of flakes or lumps, only a little coarse powder is used to assist the start of the reaction, the bulk being pellets, chopped wire, and/or pure turnings. Despite the fine size of ilmenite and rutile, the same applies to FeTi production. Owing to the relative cheapness of the ores, Al is the most expensive ingredient, and cheap aluminum is used at the expense of Ti recovery.

In aluminosilico reductions only powders are used, in the case of FeMo because the ore is fine, in the case of FeW to obtain maximum speed of reaction so as to achieve the high temperature required. The reductants are Al powder and 75 % FeSi, on the order of 0.25 mm average.

The amount of flux used is kept to a minimum in aluminothermic charges. Where sodium salts are used as auxiliary oxidants, residual Na_2O already lowers the melting point of the slag. A calcium salt is the usual flux because it has such a significant effect on the melting point of Al_2O_3 (see Fig. 4). Instead of CaO, CaF_2 often is used as its low melting point of 1418 °C assists in promoting a smooth reaction. The amount used is often 1 – 2 % of the total charge, never more than 5 %.

Significant quantities of CaO – CaF_2 are used in aluminosilico thermic reactions because it is important for their success to tie the SiO_2 produced. As can be seen from Table 4, CaO has a strong affinity for SiO_2.

After the components have been weighed out accurately, they are mixed completely in a gently acting mixer, such as a drum with lifters, V blender, or rotating cube. Duration of mixing can be determined only by practice and can be determined initially by analyzing samples taken at intervals.

The charge is then dropped into a feeding hopper.

3.3. Feeding

When a charge has been prepared accurately to produce the desired result, success depends on the efficiency of feeding. The usual method is to

control the exit valve of the feeding hopper according to the visual observation of the speed of the reaction, making slight adjustments to compensate for momentary coldness or hotness. Additional finer control is often applied by means of a handrake in the feeding chute. A fast reaction, such as that for FeV, often requires cooling, and a second small hopper may be used to feed a portion of crushed FeV slag. A FeW reaction is fed as fast as possible.

3.4. Further Processing

Pot stripping, block cleaning, and crushing require no further description than described in the introduction to Chapter 3, except to emphasize the importance of avoiding cross contamination. This is particularly the case with FeB. A small amount of B is very beneficial to a steel designed for it but an unknown amount can be disastrous.

3.5. Safety Precautions

It must be realized that exothermic production, inadequately supervised, can be a very dangerous operation. Aluminum powder and oxidants are themselves fire hazards, and risk is magnified, when they are in contact, maybe to explosive proportions.

Aluminum powder and oxidants must be stored separately and the latter kept clear of carbonaceous material. Only sufficient for a single charge should be brought to the mixing department, and, during weighing, the oxide or ore should be sandwiched between the Al powder and the auxiliary oxidant to avoid direct, concentrated contact.

Mixing plants should be grounded to avoid buildup of static electricity. During firing, overfeeding can cause violent eruptions. Lumpy $NaClO_3$ can cause explosions. In case of an inadvertent lining failure, a large enough well should be provided to accept all the charge.

The main causes of disastrous explosions are Al dust explosions, either primary, because of careless handling, or secondary, over an overfed reaction. It also has been known for the metal and slag, apparently solid, to be quenched while still liquid internally, creating a disastrous explosion.

Employees must be protected from inhalation of dust and physical contact with charge components. This is particularly the case with hexavalent compounds of Cr, which can cause the well-known chrome ulcers.

Housekeeping must be exceptional. Fine dust accumulated on roof beams has been known to combust spontaneously.

4. Other Uses of Aluminothermic Processes

A significant use of an aluminothermic process is the welding of railway and tramway line joints, where the reaction takes place in a small crucible, and the steel produced is tapped onto the joint. In a similar manner, heavy cracked steel components, such as rolls, are welded and worn parts are built up and remachined. Developments over the last few years are the repair of ingot mold stools, where the steel stream has worn a cavity, and of cracked ingot mold lugs.

The use of exothermic reactions in incendiary bombs, where the intense $Fe_2O_3 - Al$ reaction ignites the magnesium casing, is well known. Other military uses are for flares, which in the case of sea rescue give off colored smokes.

Milder reactions, damped down by insulating materials, are used in feeder head compounds, which are spread over the surface of liquid steel ingots in order to conserve the heat and minimize piping. For steel castings, similar compositions are formed into sleeves inserted in the sand mold to insure liquidity over the whole of the pouring time. Where large amounts of alloying addition are made to steel in the ladle, the cooling effect of the addition may be counteracted by the use of exothermic briquettes composed of alloy, Al, and oxidant. Minor uses are for jointing of Al and Cu cables by a $CuO - Al$ reaction, and as slow reactions for hand warmers and food cans for explorers.

5. Possible Further Developments

Wherever alloys with low content are required, aluminothermic processes are necessary, and they have been brought to such an efficiency that little further improvement can be foreseen.

Improved refractories may permit further transfer of some reactions to the arc furnace, saving Al plus auxiliary oxidant, but at present, those which can be envisaged possibly to stand up to the longer exposure are very expensive and have to compete with the self-produced refractory from an exothermic reaction.

Plasma processes are a possibility, the very high temperatures encouraging the oxide–carbon reaction, but up to now there has been no success in driving the reaction to low C levels. Here again, refractories are a problem.

A relaxation of maximum impurity levels would be of mutual economic benefit to alloy maker and steel maker. Stringent specifications for superalloys are obvious, but when the small proportion of alloy used in many steels and the wealth of purification methods used in bulk steel production are considered, then some relaxation in impurity levels should be possible, enabling use of cheaper, more impure ores. Higher Al and/or Si levels would give better recovery and, where present specifications are very low, lower oxygen levels.

1. Introduction

Aluminum [*7429-90-5*] is the most abundant metallic element in the earth's crust. It is normally found combined with other elements, and occurs rarely, if at all, in its pure state. However, elemental aluminum particles have been discovered in lunar soil [13]. Aluminum appears in a wide variety of minerals combined with oxygen, silicon, the alkali and alkaline-earth metals, and fluorine, and as hydroxides, sulfates, and phosphates. Aluminum has become the predominant nonferrous metal in use, yet it is one of the newest of the common metals. Aluminous minerals are quite stable; large amounts of energy and high temperatures are required to reduce these compounds to metal. This is the reason often given to explain why the metal has been isolated and produced commercially only in relatively recent times.

In the late 18th and early 19th centuries many famous scientists worked at isolating aluminum, including Lavoisier, Dalton, Berzelius, Davy, and Oersted. In 1825 Hans Christian Oersted discovered a method to prepare anhydrous aluminum chloride, a compound that was to play an important role in the production of the metal. Oersted is sometimes credited with the discovery of aluminum but more often that honor is accorded to Friedrich Wöhler. His isolation of aluminum in 1827 was based on the reaction in a porcelain crucible of anhydrous aluminum chloride with potassium.

In 1854, H. Sainte-Claire Deville improved the method of preparing aluminum by substituting sodium for potassium as the reductant for aluminum chloride. He was the first to

10.1002/14356007.a01_459

record that fused cryolite serves as a solvent for aluminum oxide. DEVILLE emerges as the outstanding figure in aluminum technology in the period after its discovery and before commercialization of the Hall–Héroult process. His development of the chemical reduction process raised aluminum from a laboratory curiosity to a useful metal.

The chemical production process was further refined throughout the second half of the 19th century and the aluminum industry grew significantly during this period. Chemical production of aluminum by reduction of cryolite or aluminum fluoride with sodium or potassium was also under development in the late 19th century. The metal exhibited at the Paris Exposition of 1889 was produced at Alliance Aluminium of London, probably by sodiothermic reduction of cryolite. Reduction methods were used into the 1890s, when electrolyte production became dominant.

In the late 19th century many unsuccessful attempts were made to electrolyze aluminum from aqueous solutions. Aluminum was first prepared electrolytically by a method discovered independently in 1854 by DEVILLE in France and BUNSEN in Germany. A sodium chloride-aluminum chloride fusion was electrolyzed in a porcelain crucible using carbon electrodes. Production based on this electrolysis of aluminum chloride was begun in 1975 but operation was suspended in 1982. Development of the process is continuing (see Section 4.5).

For a discussion of the Hall–Héroult electrolytic process, see Section 4.1.

2. Properties of Pure Aluminum

Certain physical and chemical properties of aluminum depend primarily on purity. There is no generally accepted nomenclature for the degrees of purity of aluminum. The following classification is suggested:

% Aluminum	Designation
<99.5	alloy or scrap
99.5 – 99.9	commercial purity
99.9 – 99.99	high purity
>99.99	super purity

The aluminum produced by the Hall–Héroult process is of commercial purity. Iron and silicon are the predominant impurities. Aluminum of super purity, produced by the three-layer electrolytic process, first became available in 1920 (see Chap. 5). The properties of this grade of metal have been studied extensively. Methods for preparing aluminum of even higher purity include zone refining, fractional crystallization, and preparation from aluminum alkyls. Electrical resistivity at low temperatures is employed as a measure of purity for high purity and super purity aluminum. Newer methods for analysis of trace impurities, including activation analysis, have improved the sensitivity and scope of analyses for very pure materials. Aluminum purer than 99.9999 % has been prepared and characterized [14].

Many applications of aluminum and its alloys are based upon its inherent properties of low density, high electrical and thermal conductivities, high reflectivity, and great resistance to corrosion. Pure aluminum is soft and lacks strength, but it can be alloyed with many other elements to increase strength and impart a number of useful properties. Alloys of aluminum are light, strong, and readily formable by many metal-working processes; they can be cast, joined, or machined easily and accept a wide variety of finishes. The properties and processing of alloys are discussed under the keyword → Aluminum Alloys.

2.1. Mechanical Properties

The mechanical properties of aluminum and its alloys are discussed under → Aluminum Alloys. Some mechanical properties of aluminum of several purities are given in Table 1 [15].

Table 1. Mechanical properties of pure aluminum at room temperature

Purity	Tensile strength		Elongation in 50 mm
%	MPa	ksi *	%
99.99	45	6.5	50
99.8	60	8.7	45
99.6	70	10.2	43

* kips (1000 pounds) per square inch

The data are from different sources and caution should be exercised in any direct comparison. Difficulties occur because of problems in anal-

ysis, temper of the specimen, and test methods. However, even small amounts of impurities present in commercial aluminum raise the tensile strength and hardness over that of the purest aluminum in the table.

2.2. Physical Properties

The physical properties of pure aluminum are summarized in Table 2 [15].

Table 2. Physical properties of pure aluminum

Property	Value
mp	933.5 K
bp	2767 K
Heat of fusion	397 J/g
Heat of vaporization	1.08×10^{-4} J/g
Heat capacity	$0.90\,\mathrm{J\,g^{-1}K^{-1}}$
Density (solid)	
theoretical density based on lattice spacing	$2699\,\mathrm{kg/m^3}$
polycrystalline material	$2697-2699\,\mathrm{kg/m^3}$
Density (liquid)	$2357\,\mathrm{kg/m^3}$ at 973 K $2304\,\mathrm{kg/m^3}$ at 1173 K
Thermal neutron cross section	$(2.32\pm0.03)\times10^{-25}\,\mathrm{cm^2}$ (0.232±0.003 barn)
Lattice constant (length of unit cube)	4.0496×10^{-10} m at 298 K
Coefficient of expansion	23×10^{-6}/K at 293 K
Thermal conductivity	$2.37\,\mathrm{W\,cm^{-1}K^{-1}}$ at 298 K
Volume resistivity	$2.655\times10^{-8}\,\Omega\,\mathrm{m}$
Magnetic susceptibility	$16\times10^{-3}\,\mathrm{mm^{-3}\,mol^{-1}}$ at 298 K
Surface tension	8.68×10^{-3} N/cm at the *mp*
Viscosity	$0.0012\,\mathrm{Pa\cdot s}$ at the *mp*

Atomic Structure, Nuclear Properties [15]. Aluminum has an atomic number of 13 and atomic mass of 26.98154 based on ^{12}C. The only abundant isotope, ^{27}Al, is stable and consists of 14 neutrons and 13 protons. Except for a single isotope, ^{26}Al, which has a half-life of 10^6 years, all isotopes have half-lifes of less than 8 s and are of negligible abundance. The naturally occurring isotope has a low cross section for thermal neutrons of $2.3\times10^{-25}\,\mathrm{cm^2}$, increasing in an irregular manner to $6\times10^{-25}\,\mathrm{cm^2}$ at 700 – 800 MeV. The nuclear magnetic moment is $1.84\times10^{-26}\,\mathrm{A\cdot m^2}$.

Crystal Structure. Aluminum crystallizes in a face-centered cubic lattice that is stable from 4 K to the melting point. The coordination number is 12 with four atoms to the unit cell. The edge length of the unit lattice cube for pure aluminum is 4.049596×10^{-10} m at 298 K. Hence, the atomic diameter of aluminum is 2.86×10^{-10} m and its atomic volume $9.999\times10^{-6}\,\mathrm{m^3/mol}$. The lattice parameter is affected only slightly by impurities.

Thermal Expansion. Values for the coefficient of thermal expansion are given in Table 3 [15]. The coefficient of thermal expansion is probably isotropic, meaning it is the same in all directions.

Table 3. Thermal expansion coefficient of pure aluminum

Temperature, K	α ($\times10^{-6}$/K)	Temperature, K	α ($\times10^{-6}$/K)
25	0.5	400	24.9
50	3.5	500	26.5
75	8.1	600	28.2
100	12.0	700	30.4
150	17.1	800	33.5
200	20.2	900	37.3
293	23		

Thermal Conductivity. Above 100 K the thermal conductivity of well-annealed 99.99 % aluminum is relatively insensitive to the impurity level. Below 100 K thermal conductivity becomes highly sensitive to the level of impurities. Values for thermal conductivity are given in Table 4 [15].

273.2	2.36	1500	1.07
298.2	2.37		

Electrical Resistivity. The application of aluminum as an electrical conductor depends upon the low electrical resistivity of unalloyed aluminum. The electrical conductivity of pure aluminum at room temperature is 64.94 % of that specified for copper in the International Annealed Copper Standard (IACS). At temperatures below 50 K, the electrical resistivity of aluminum is less than that of copper and silver of very high purity. Aluminum becomes superconducting below 1.2 K.

The resistivity of aluminum below 100 K is highly sensitive to purity. The *residual resistivity ratio* (RRR), or the ratio of electrical resistivity at room temperature to that at 4.2 K (boiling point of helium), is sometimes used as a measure of purity. Resistivity ratios of more than 3×10^4 have been reported for 99.999 % aluminum.

Values for the electrical resistivity of aluminum are given in tabular form (Table 5) and schematically (Fig. 1).

Table 5. Electrical resistivity of pure aluminum

Symbol	Temperature, K	Resistivity, $\mu\Omega\cdot$cm	Sample

3. Chemical Properties

The 13 electrons in the aluminum atom are distributed: $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^1$. With few exceptions the valence of aluminum in chemical compounds is 3 +. At elevated temperatures aluminum is monovalent in gaseous molecules, such as AlCl, AlF, and Al_2O. Such species disproportionate at lower temperatures into the normal trivalent condensed compounds and elemental aluminum.

For reactions of aluminum not covered in this chapter, see → Aluminum Compounds, Inorganic and → Aluminum Compounds, Organic.

3.1. Oxidation of Aluminum

Although aluminum is one of the most reactive of the common commercial metals, it is remarkably stable in many oxidizing environments. It

owes its stability to the continuous film of aluminum oxide that rapidly grows on a nascent aluminum surface exposed to oxygen, water, or other oxidants. The molecular volume of the oxide is about 1.3 times greater than that of the aluminum consumed in the oxidation reaction. The surface layer, therefore, is under compressive stress and rapidly heals when damaged. In dry oxygen, the surface layer attains a limiting thickness that is a function of temperature. At room temperature this thickness is about 2.5 – 3.0 nm.

Film thickness is also a function of the amount of water vapor present. At room temperature and 100 % relative humidity, about twice as much oxide is formed as in dry oxygen. In both cases, however, the same rate laws apply. Two film layers generally form in wet environments; the continuous oxide layer closest to the metal surface changes to a hydroxylated film at the solid-gas interface. At higher temperatures and on aluminum alloys, especially those containing magnesium and copper, more complex film structures develop, and oxide growth no longer can be described by simple time laws [16].

3.2. Reactions with Aqueous Solutions

Large pieces of aluminum of purity greater than 99.95 % resist attack by most acids but dissolve in aqua regia. Therefore, aluminum is used to store nitric acid, concentrated sulfuric acid, organic acids, and many other reagents. However, its oxide film dissolves in alkaline solutions; corrosion is rapid, producing soluble alkali-metal aluminate and hydrogen:

$$2\,Al + 2\,OH^- + 6\,H_2O \rightarrow 2\,[Al(OH)_4]^- + 3\,H_2(g)$$

Aluminum is amphoteric and can react with mineral acids to form soluble salts and evolve hydrogen:

$$2\,Al + 6\,H_3O^+ + 6\,H_2O \rightarrow 2\,[Al(H_2O)_6]^{3+} + 3\,H_2(g)$$

Molten aluminum can react explosively with water [17], [18]. The mechanism of the reaction is not well understood. Molten aluminum should not be allowed in contact with moist tools or containers.

3.3. Reactions at High Temperatures

Molten aluminum reduces many compounds containing oxygen (→ Aluminothermic Processes). These reactions are used in the manufacture of certain metals and alloys by the thermite reaction, which is the reaction of a metal oxide with aluminum to produce aluminum oxide (Al_2O_3) and the free metal.

Aluminum reduces silicates, particularly glasses. The reaction can start well below the melting point of aluminum.

3.4. Corrosion

Atmospheric corrosion is generally electrochemical in nature, depending on current flow between anodic and cathodic areas. Attack is often nonuniform and limited to specific areas of the surface. The corrosion resistance of some alloy sheet can be improved by cladding the sheet with a thin layer of unalloyed aluminum; however, the aluminum must be anodic to the base metal. Aluminum performs poorly in direct contact with more noble metals in the presence of an electrolyte; galvanic attack of aluminum may take place near the contact area.

3.5. Gases and Aluminum

Hydrogen [*1333-74-0*] is appreciably soluble in both solid and molten aluminum. Other gases reported to be present occur when nonmetallics in the metal react with the environment. Molten aluminum reacts readily with carbon monoxide [*630-08-0*] and carbon dioxide [*124-38-9*]; it also reacts with water vapor in the atmosphere, adsorbed water, water present in hydrated oxide films on scrap, and water adsorbed on or combined in refractories. Solid aluminum reacts with moisture in the atmosphere of a furnace to form oxides and hydrogen. Hydrogen is considerably less soluble in solid than in molten aluminum. The gas diffuses out of the metal at a rate determined by the temperature. However, when the reaction of aluminum with water vapor leads to a high activity of hydrogen at the solid-gas interface, the concentration gradient can be reversed. As a result, the rate of outgassing is decreased

and a higher level of hydrogen is retained in the metal. In solid aluminum, hydrogen in excess of the solution limit can precipitate as H_2 at grain boundaries, thus lowering the hydrogen ion concentration and in turn further facilitating the diffusion of hydrogen ions from the interface into the metal.

4. Production

The only method now used industrially to produce primary aluminum is the Hall–Héroult process. Production of aluminum before its development was discussed previously in this article. Alternate means of producing aluminum are treated in Section 4.5.

4.1. History of the Electrolytic Reduction of Alumina

The technological elements of the process – electrolysis of fused salts to produce metals (including aluminum), the use of cryolite as a flux to dissolve alumina, and the use of carbon electrodes – had been exploited for some time prior to 1886. The workable electrolytic process was discovered independently, and almost simultaneously, in early 1886 by CHARLES MARTIN HALL in Oberlin, Ohio, and PAUL L. T. HÉROULT in Gentilly, France. Both these young scientists were familiar with the work of SAINTE-CLAIRE DEVILLE.

In less than three years, the invention had been implemented industrially in North America and in Europe. In November 1888 aluminum was first produced commercially by the electrolytic reduction of alumina by HALL and others in a company that later was to become the Aluminum Company of America. At about the same time, HÉROULT was associated with a company (later to be known as Alusuisse) that operated aluminum electrowinning cells at Neuhausen, Switzerland.

KARL J. BAYER, an Austrian chemist, was issued a patent, DE 43977, in July 1887 for an improved method of producing alumina from bauxite. Bauxite [*1318-16-7*], discovered by P. BERTHIER in 1821, is named for Les Baux, the village in the south of France near which it was first found. With the development of a process to produce pure aluminum oxide from this abundant ore, the technology was then complete to spur rapid growth of the aluminum industry in Europe and North America in the last decade of the 19th century. The increase in the production of primary aluminum during the past hundred years is shown in Figure 2 [19].

Figure 2. Annual world production of primary aluminum 1854 – 1982 [7]

4.2. Raw Materials

Carbon. In the industrial electrowinning (separation by electrolysis) of aluminum, part of the energy for reducing alumina is supplied as electricity and part comes from consumption of the carbon *anode.* Carbon is also used as the cathode lining. Because 0.4 – 0.5 kg of anode is consumed for each kilogram of aluminum produced, this represents the major carbon requirement. Because the ash from the carbon will contaminate either the aluminum produced or the electrolyte, high-purity carbon is desirable. Certain impurities, such as vanadium, are particularly harmful in that they catalyze air burning of the carbon. Other impurities, such as phosphorus, accumulate in the electrolyte and undergo cyclic redox reactions (partial reduction followed by reoxidation), consuming electric current without producing product. The coke residue from petroleum refining is quite pure and, therefore, has been the major source of carbon for anodes. The structure of petroleum coke (→ Petroleum Coke) varies depending on the nature of the petroleum feedstocks used at the refinery, the refinery flowstream, and the coking conditions used. This coke produced at about

500 °C requires calcining at about 1200 °C to remove volatile constituents and increase its density before it is blended into the anode mix. After calcination, the coke is ground and mixed with crushed spent anodes and sufficient coal-tar pitch to allow molding into anode blocks by pressing or by vibrating. They are baked at 1000 – 1200 °C, causing the pitch to carbonize, forming strong carbon blocks. These blocks are made with one or more sockets into each of which is fastened a steel stub by pouring cast iron around it. These stubs both conduct electric current into the anode and support the anodes in the cell. The cost of prebaked carbon anodes in the United States was about $ 0.40/kg ($ 0.15/pound) in 1983.

Anthracite has been the major constituent in the cell *cathode* blocks, although graphite and metallurgical coke have been used to some extent. The anthracite is calcined at 1200 °C or higher, crushed and sized, mixed with coal-tar pitch, molded into blocks, and baked. These blocks, mortared together with a carbonaceous seam mix, form the pot lining, which is the container for both the aluminum and the electrolyte. High purity is not as important for the cathode blocks because leaching of impurities is very slow. Consumption of cathode carbon amounts to 0.02 – 0.04 kg of carbon per kilogram of aluminum produced. The life of a pot (typically 2 – 6 years) generally is terminated by failure of the carbon pot lining.

Aluminum Oxide. Depending on its purity and losses in handling, 1.90 – 1.95 kg of alumina are consumed in producing 1 kg of aluminum. The cost of alumina at United States smelting facilities was $ 0.20 – 0.26/kg ($ 0.09 – 0.12/pound) in 1983. The preparation of metallurgical alumina and its required physical and chemical properties are discussed under → Aluminum Oxide.

Electrolyte Materials. The electrolyte for electrowinning aluminum is basically a solution of aluminum oxide in cryolite [*15096-52-3*]. The presence of cryolite is essential for dissolution of alumina. Cryolite usually comprises more than 75 % of the electrolyte which typically also contains calcium fluoride (4 – 8 %), excess aluminum fluoride (5 – 15 %), alumina (1 – 6 %), and sometimes lithium fluoride [*7789-24-4*] (0 – 5 %) and magnesium fluoride [*7783-40-6*] (0 – 5 %). These additives lower operating temperature and increase current efficiency.

The mineral cryolite is the double fluoride of sodium and aluminum and has a stoichiometry very near the formula Na_3AlF_6 and a melting point of about 1010 °C. It has been found in substantial quantities only in Greenland, and was mined extensively there in the early 20th century but now is essentially exhausted. Synthetic cryolite can be produced by reacting hydrofluoric acid with an alkaline sodium aluminate solution:

$$6\,HF + 2\,NaOH + NaAlO_2 \rightarrow Na_3AlF_6 + 4\,H_2O$$

Cryolite also can be recovered from used pot linings. The lining is crushed and treated with dilute sodium hydroxide solution to dissolve fluorides. After being filtered, the solution is neutralized with carbon dioxide to precipitate the cryolite.

Cryolite is produced directly in reduction cells by reaction of the soda impurity in the feed alumina with added aluminum fluoride (→ Fluorine Compounds, Inorganic):

$$3\,Na_2O + 4\,AlF_3 \rightarrow 2\,Na_3AlF_6 + Al_2O_3 \qquad (1)$$

Electrolyte generated by the above reaction must be tapped from the cells periodically. In modern smelters with dry scrubbing equipment for fume treatment and cell lives greater than 3 years, cryolite is a byproduct rather than a raw material in producing aluminum.

Synthetic cryolite could be purchased in the United States for $ 500 – 600/t in 1983.

Aluminum Fluoride. Aluminum fluoride, AlF_3 [*7784-18-1*], may comprise as much as 15 wt% of the electrolyte in excess of the amount represented by the cryolite composition. Aluminum fluoride is consumed during normal operation by three major mechanisms. First, losses of aluminum fluoride by vaporization are appreciable; the most volatile species present in the electrolyte is sodium tetrafluoroaluminate [*13821-15-3*], $NaAlF_4$, having a partial pressure of 200 – 600 Pa over the operating melt, depending on composition and temperature (→ Fluorine Compounds, Inorganic). Second, aluminum fluoride is depleted by hydrolysis:

$$2\,AlF_3 + 3\,H_2O \rightarrow Al_2O_3 + 6\,HF$$

And finally, aluminum fluoride is consumed by reaction with the soda present in feed alumina (Eq. 1).

Fume capture and scrubbing efficiencies have improved aluminum smelters. Fluoride previously lost by vaporization of $NaAlF_4$ and hydrolysis of bath is now almost completely recycled to the cells. Nevertheless, aluminum fluoride consumption amounts to 0.02 – 0.04 kg AlF_3 per kilogram of aluminum product. In 1983 technical anhydrous aluminum fluoride could be purchased in the United States for about $ 350/t.

4.3. Hall–Héroult Cell for Aluminum Production

All commercial production of aluminum today is done in Hall–Héroult cells. Employing prebaked carbon anodes or self-baking Söderberg anodes. The Hall–Héroult cell with *prebaked anodes* is shown in Figure 3. Essentially pure alumina is fed into the previously discussed cryolite base electrolyte. Electric current deposits aluminum into a pool of molten aluminum held under the electrolyte in the carbon lined cavity of the cell. Oxygen from the alumina deposits electrolytically onto the carbon anode dipping into the electrolyte and reacts with (burns) the anode. Cells typically range from 9 to 12 m long, 3 to 4 m wide, and 1 to 1.2 m high. Thermal insulation surrounds the carbon lining of the cell to control heat losses. Although carbon is the material known to withstand best the combined corrosive action of molten fluorides and molten aluminum, even carbon would have a very limited life in contact with the electrolyte at the sides of the cell were it not protected by a layer of frozen electrolyte. The thermal insulation is adjusted carefully to maintain a protective coating on the walls but not on the bottom, which must remain substantially bare for electrical contact. Steel collector bars in the carbon cathode conduct electric current from the cell. These bars are inserted into holes that have been sized carefully so that thermal expansion forms a tight electrical contact, or cemented in place with a carbonaceous cement containing metal particles, or bonded in place with cast iron.

The electrical resistivity of prebaked anodes ranges from 0.005 to 0.006 Ω cm. Current density at the anode face is 0.6 – 1.3 A/cm^2.

Figure 3. Hall–Héroult cell with prebaked anodes

The *Söderberg anode* (Fig. 4) uses a premixed "paste" of petroleum coke and coal-tar pitch. This mixture is added at the top of a rectangular steel casing that is typically 6 – 8 m long, 2 m wide, and 1 m high. Heat from the electrolyte and heat from the electric current passing through the anode bakes the carbonaceous mix as it progresses through the casing.

Figure 4. Aluminum electrolyzing cell with Söderberg anode
a) Manifold gas; b) Steel shell; c) Current collector bars; d) Frozen ledge; e) Molten electrolyte; f) Coke and tar paste; g) Current supplying pins

The baked portion extends past the casing and into the molten electrolyte. Baked mix replaces anode being consumed at the bottom surface. Electric current enters the anode through either

vertical or sloping steel spikes. These spikes are pulled and reset to a higher level as they approach the lower surface. Söderberg anodes have an electrical resistivity about 30 % higher than that of prebaked anodes. Because of the resulting lower power efficiency and the greater difficulty in collecting and disposing of baking fumes, Söderberg anodes are being replaced by prebaked anodes, even though the former save the capital, labor, and energy required to manufacture the latter.

4.3.1. Electrolyte

Pure cryolite melts at about 1010 °C. Alumina and other additives lower the melting point, allowing operation at 940 – 980 °C. The cryolite-aluminum fluoride-alumina system (Fig. 5) [20] has binary eutectic points at 961 °C and 694 °C and a ternary one at 684 °C. Calcium fluoride and lithium fluoride further reduce the liquidus temperature (Figs. 6 [21] and 7 [22]). *Calcium fluoride* is seldom added intentionally. Because of a small amount of calcium oxide impurity in the alumina, it attains a steady-state concentration of 3 – 8 % in the melt. At this level calcium is codeposited into the aluminum and emitted in the off-gas at a rate equal to its introduction. Magnesium fluoride accumulates to 0.1 – 0.3 %, in the electrolyte by the same mechanism as calcium fluoride. Some operators add up to 5 % MgF_2 because it expels carbon dust from the electrolyte by decreasing the electrolyte's ability to wet carbon.

Figure 5. The Na_3AlF_6–AlF_3–Al_2O_3 system [20]

Calcium fluoride, in addition to lowering the liquidus temperature, decreases the vapor pressure and solubility of reduced species in the electrolyte for better current efficiency. Detrimentally, it lowers alumina solubility and electrical conductivity and increases density, viscosity, and surface tension of the electrolyte. *Lithium fluoride,* in addition to lowering the melting point, decreases the vapor pressure, density, reduced species solubility, and viscosity; it also increases electrical conductivity. The only negative effect appears to be lowered alumina solubility. Its high cost, however, requires that its benefits be weighed against the price. *Aluminum fluoride* decreases solubility of reduced species and lowers surface tension, viscosity, and density. It has the undesirable effects of decreasing alumina solubility and electrical conductivity and increasing vapor pressure. Aluminum fluoride

Figure 6. The Na_3AlF_6–Al_2O_3–CaF_2 system [21]

Figure 7. The Na_3AlF_6–Li_3AlF_6–Al_2O_3 system [22]

acts as a Lewis acid with sodium fluoride acting as a Lewis base. Neutrality has been defined arbitrarily as a molar ratio of sodium fluoride to aluminum fluoride of 3 : 1. Control of electrolyte acidity or the NaF : AlF_3 molar ratio, referred to as the *cryolite ratio* (R_c), is of importance to cell operation. Lithium fluoride is a slightly weaker Lewis base than sodium fluoride. Magnesium fluoride and calcium fluoride are weak Lewis acids.

Ionic Structure of the Melt. There is general agreement that molten cryolite is completely ionized to sodium ions and hexafluoroaluminate ions:

$$Na_3AlF_6 \rightarrow 3\,Na^+ + [AlF_6]^{3-}$$

Also it is well established that the hexafluoroaluminate ion dissociates further:

$$[AlF_6]^{3-} \rightarrow [AlF_4]^- + 2\,F^-$$

At $R_c = 3$, $[AlF_6]^{3-}$ is about 30 % dissociated [23]. Raman spectroscopy has showed that the dissociation increases with decreasing cryolite ratio to complete dissociation at $R_c = 1$ [24].

The nature of the species formed when alumina is added is not so well established. Combination of the results of cryoscopic measurements, Raman spectrographic data, and equilibrium studies and vapor pressure measurements (reviewed in [23]) leads to the conclusion that $[Al_2O_2F_4]^{2-}$ and $[Al_2OF_6]^{2-}$ are the two major oxygen-containing ions in the melt. Possible reactions for their formation are:

$$2\,Al_2O_3 + 2\,[AlF_6]^{3-} \rightarrow 3\,[Al_2O_2F_4]^{2-}$$

$$Al_2O_3 + 4\,[AlF_6]^{3-} \rightarrow 3\,[Al_2OF_6]^{2-} + 6\,F^-$$

4.3.2. Electrode Reactions

Cathode Reaction. Even though Na^+ is the principal current carrier, it does not discharge at the cathode. The reversible electromotive force for the formation of liquid aluminum is about 0.24 V lower than that for the formation of sodium gas at 101.3 kPa (1 atm) for the range of compositions and temperatures used industrially. Bowman [25], using cyclic voltammetry, stationary electrode polarography, differential pulse polarography, and chronopotentiometry, found evidence only for a reversible three-electron transfer process. There was no evidence for a chemical reaction, either preceding or following the electron-transfer process. This ruled out discharge of sodium at low activity followed by a chemical reaction to form aluminum, and also eliminated dissociation of the $[AlF_6]^{3-}$ or $[AlF_4]^-$ to form Al^{3+} and F^- ions in the double layer preceding charge transfer. Rolin, et al. [26] believed this latter process does take place. If so, dissociation must be too rapid to be detected by Bowman's techniques.

The cathode overvoltage can be represented by [27]:

$$\eta_{cc} = [RT\,(1.375 - 0.125\,R_c)\,/\,(1.5\,F)]\,\ln\,(i/0.25) \quad (2)$$

where R is the gas constant, T is the temperature (K), R_c is the mole ratio NaF : AlF_3, F is the Faraday constant, and i is the electrode's current density (in A/cm^2). Although this relationship mathematically looks like activation overvoltage, actually the cathode overvoltage is caused by an increase in the NaF : AlF_3 ratio at the aluminum surface [28]. Sodium ions carry the current while complex aluminum anions discharge. This requires a diffusional flux of $[AlF_6]^{3-}$ and $[AlF_4]^-$ ions to the cathode interface with a similar diffusional flux of Na^+ and F^- ions away from the interface. Using Fick's first law, the resulting concentration gradients were calculated and good agreement was found between the measured overvoltages and the electromotive forces between the two aluminum half-cells, one containing electrolyte of the bulk composition and the other, electrolyte corresponding to the calculated interfacial composition.

Anode Reactions. The primary anode reaction can be written:

$$C + 2\,O^{2-} \rightarrow CO_2 + 4\,e^-$$

However, O^{2-} ion is not present in the bulk electrolyte; instead, oxygen is present as structurally large complexes, i.e., $[Al_2OF_6]^{2-}$ and $[Al_2O_2F_4]^{2-}$. Thermodynamically, oxygen depositing onto carbon at 950 – 1000 °C should equilibrate to about 99 % CO and 1 % CO_2.

However, based on either net carbon consumption or the volume of gas produced, the primary anode product is essentially all CO_2. The high anodic overvoltage implies that reaction kinetics cause this surprising displacement from thermodynamic equilibrium. Rotating disk [29] and impedance [30] measurements indicate that there is a small diffusional overvoltage, probably caused by reaction within the pores of the electrode. Using the general treatment for heterogeneous reaction control [31], overvoltage data can be expressed by the relationship:

$$\eta_{SA} = (vRT/pnF)\ \ln\left(i/i^0\right) \tag{3}$$

where v is the number of executions of rate-controlling steps to produce one overall step, p is the reaction order, n is the number of electrons transferred in one overall step, and i^0 is the reaction limiting current density. The reaction order, $p = 0.57$, was found from measurements of overvoltage versus current density [32]. In industrial practice, the reaction order ranges from 0.4 to 0.6, varying with carbon reactivity and porosity. The reaction-limiting current density, i^0, goes from 0.0039 to 0.0085 A/cm^2 as alumina concentration varies from 2 to 8 wt %. The reaction order also has been determined [32] from the rate of change of the limiting current with reactive species concentration and a similar value obtained:

$$p = \frac{\mathrm{d}\ln i^0}{\mathrm{d}\ln c_{Al_2O_3}} = 0.56 \tag{4}$$

Measurements [33] of the ordinary combustion of graphite have shown that when oxygen reacts both in pores and on the surface, a chemical reaction of approximately half-order results. Linear sweep voltammograms showed voltage peaks with increasing current density corresponding to discharge of CO_2, COF_2, and CF_4 [34].

The following anode reaction mechanism is consistent with these observations. Oxyfluoride ions dissociate within the double layer to oxygen ions:

$$[Al_2O_2F_4]^{2-} \rightarrow O^{2-} + Al_2OF_4$$

$$Al_2OF_4 + [Al_2OF_6]^{2-} \rightleftharpoons [Al_2O_2F_4]^{2-} + 2\,AlF_3$$

Oxygen ions discharge upon the carbon surface (surf) forming an activated complex, CO:

$$C\,(surf) + O^{2-} \rightarrow C{*}O^{-}\,(surf) + e^{-}$$

$$C{*}O^{-}\,(surf) \rightarrow C{*}O\,(surf) + e^{-}$$

The activated complex converts very slowly to CO (g) through an adsorbed (ads) intermediate:

$$C{*}O(surf) \rightarrow CO\,(ads)\ \text{slow}$$

$$CO(ads) \rightarrow CO\,(g)\ \text{slow}$$

Carbon burning in pure oxygen at 940 – 970 °C has a combustion rate equivalent to between 0.1 and 0.2 mA/cm^2. One would expect this reaction to proceed at a similarly slow rate. As available surface sites become covered with C∗O, oxygen is deposed at higher energy (overvoltage) onto a carbon site already bonded to oxygen, producing unstable $[C{*}O_2]^{-}$, which breaks carbon to carbon bonds almost immediately as it is formed:

$$C{*}O\,(surf) + O^{2-} \rightarrow [C{*}O_2]^{-}\,(surf) + e^{-}$$

$$[C{*}O_2]^{-}\,(surf) \rightarrow CO_2\,(ads) + e^{-}$$

$$CO_2\,(ads) \rightarrow CO_2\,(g)$$

The adsorbed CO_2 quickly desorbs as CO_2 (g). This mechanism explains both the high anodic overvoltage and the primary production of CO_2 instead of the thermodynamically favored CO.

When there is insufficient alumina in the electrolyte, the cell experiences a phenomenon called *anode effect.* Bubbles grow larger and larger on the anode until the electrolyte no longer wets the anode. With a constant potential the current falls to a low value; but with the constant current source used industrially, the cell potential rises to $\geqq 30$ V. Current then penetrates the gas film by a multitude of small electric arcs or sparks. The gas produced at the anode changes from CO_2 to CO, with significant quantities (3 – 25 %) of CF_4 and minor amounts of C_2F_6 generated. Fluorocarbon compounds most likely deposit on the surface of the anode and trigger the anode effect. As alumina is depleted, anode overvoltage increases. At about 1.2 V anode overpotential, sufficient thermodynamic activity of fluorine is produced to cause fluorine to bond to the carbon. Even though these low-surface-energy carbon-fluorine compounds decompose on the surface to CF_4 and C_2F_6 at cell temperature, their rate of formation can exceed the rate of thermal decomposition, producing high coverage. Once the cell is on anode effect,

restoring the alumina concentration is not sufficient to return it to normal operation. The gas film must be broken by splashing aluminum, by interrupting the current momentarily, or by lowering the anodes to expose new areas not contaminated with fluorine.

4.3.3. Current Efficiency

According to Faraday's law, 1 kA h of electric current should produce 0.3356 kg of aluminum, but only 85 – 95 % of this amount is obtained. The principal loss mechanism is recombination of anodic and cathodic products. Reduced species go into solution in the electrolyte at the aluminum-electrolyte interface (Fig. 8). Disagreement exists over whether the dissolved species is metallic sodium, monovalent aluminum, subvalent sodium, colloidal aluminum, or a combination of these species. Equation (4) produces a thermodynamic activity of sodium in the melt, whereas Equation (5) produces an activity of aluminum monofluoride.

$$\mathrm{Al(l)} + 3\,\mathrm{NaF(soln)} \rightleftharpoons 3\,\mathrm{Na(soln)} + \mathrm{AlF_3(soln)} \tag{4}$$

$$2\,\mathrm{Al(l)} + \mathrm{AlF_3(soln)} \rightleftharpoons 3\,\mathrm{AlF(soln)} \tag{5}$$

Figure 8. Current efficiency loss by metal reoxidation

Metal going into solution must first diffuse through the metal-electrolyte boundary layer (Fig. 8). The metal is then transported by convection to the vicinity of the anode. Here it reacts with carbon dioxide. Chemical reactions appear to be fast compared to mass transport. The rate-controlling step was previously assumed to be diffusion of dissolved metal through the boundary layer at the metal-electrolyte interface. However, ref. [35] indicates mixed control with diffusion at both the aluminum-electrolyte interface and the bubble-electrolyte interface being important.

There are several mechanisms accounting for additional minor losses in current efficiency. New cell linings absorb sodium, with Equation (4) maintaining an equilibrium activity of sodium. Fortunately, the lining saturates early in the cell's life but until this occurs, current efficiency is low. When a metal dissolves in a molten salt it usually imparts electronic conductivity to the melt, thereby lowering current efficiency. Some investigators have found a small electronic conductance for cryolite-base melts but others have not. Such elements as phosphorus and vanadium, which can be reduced partially at the cathode and then reoxidized at the anode, lower efficiency.

4.3.4. Cell Voltage

The voltage of a Hall–Héroult cell is made up of a number of components:

$$E_{\mathrm{cell}} = E^0 + \eta_{\mathrm{CA}} + \eta_{\mathrm{CC}} + \eta_{\mathrm{SA}} + \eta_{\mathrm{SC}} - I\,(R_{\mathrm{A}} + R_{\mathrm{B}} + R_{\mathrm{C}} + R_{\mathrm{X}})$$

where E^0 is the thermodynamic equilibrium voltage described under Thermodynamic Considerations (Section 4.4); η_{CA} is the concentration overpotential at the anode; η_{SA} is the surface overpotential at the anode described by Equation (3); η_{CC} is the concentration overpotential at the cathode described by Equation (2); η_{SC} is the surface overpotential at the cathode, generally negligible; I is the total cell current; R_{A} is the electrical resistance of the anodes or anode; R_{B} is the effective resistance of the bath, allowing for fanning out of current as it flows from anode to cathode and the increased bath resistivity caused by gas bubbles (for details, see [27]); R_{C} is the cathode resistance; and R_{X} is the resistance external to the cell but included in calculating power consumption. The anode concentration overpotential can be calculated by:

$$\eta_{\mathrm{CA}} = (RT/2F)\,\ln\,[i_{\mathrm{c}}/\,(i_{\mathrm{c}} - i)] \tag{5}$$

The quantity i_{c} is the concentration-limited current density and it varies between 1.0±

0.5 A/cm^2 at 1 wt % Al_2O_3 and 15 A/cm^2 at 8 wt % Al_2O_3. The specific power consumption in kilowatt-hours per kilogram of aluminum can be calculated:

$$\text{kW h/kg} = 298.06\, E_{\text{cell}} / \%\, CE$$

where % CE is the percentage current efficiency or Faraday efficiency and E_{cell} is the cell voltage.

4.3.5. Heat Balance

Heat balance considerations are important in designing and operating a cell at the optimum temperature. Calculation is complicated by simultaneous heat flow and heat generation in conductors that carry electric current into and out of the cell. More than 50 % of the heat loss may occur through the anodes and top crust. The sidewalls must be protected from erosion by a ledge of frozen electrolyte maintained by extracting the exact amount of heat required for the desired ledge thickness. These calculations have been described [36], [37]. The complex geometry and the interaction between heat flow and electrical flow generally require a computer using either a finite element or finite difference technique for heat balances. Figure 9 [38] shows a typical heat loss distribution for a center-fed cell and Figure 10 [38], the typical temperature distribution.

Figure 9. Cell heat loss distribution [38]

Figure 10. Cell lining isotherms [38]
Dashed line: measured profile

4.3.6. Fluid Dynamics

The large electric currents used in modern cells generate relatively strong magnetic fields within the cell. These magnetic fields interact with electric currents and exert Lorentz forces, producing movement of liquid conductors. Three types of magnetic disturbances have been observed: a vertical or static displacement of the metal pad, a circulating flow within the metal pad with velocities as high as 20 cm/s, and finally a wave motion in the metal pad. The last is probably the most harmful because waves may lead to electrical short circuiting. Calculation of the magnetic fields and electric current flow patterns is complicated. Computer programs have been designed to make these calculations and describe the fluid-dynamic consequences. These calculations have been refined to the point where cells of over 2.5×10^5 A have been designed and operated with high efficiency. Natural convection caused by temperature gradients or composition differences in the electrolyte are insignificant compared with the movement induced by magnetic forces and gas bubbles. Gas bubbles produce significant stirring in the electrolyte and are the dominant force in bath movement, whereas electromagnetic forces predominate in metal pad movement.

4.4. Thermodynamic Considerations

The thermochemistry of constituents of the electrolyte and of the electrolyte-aluminum system is treated in [23]. Thermodynamic data used in the following section are from the *JANAF* (Joint Army-Navy-Air Force) *Thermochemical Tables* [39] and the 1978 supplement to the tables [40].

For pure α-alumina, reduction to aluminum can be represented:

$$1/2\ \alpha\text{-}Al_2O_3(s) \rightarrow Al(l) + 3/4\ O_2(g)$$

At 960 °C (1233 K), $\Delta G^0_{1233} = +642.12$ kJ and $\Delta H^0_{1233} = +845.62$ kJ.

In the industrial production of aluminum, a portion of the energy is supplied by the combustion of carbon anodes to carbon dioxide. The overall cell reaction can be represented:

$$1/2\ \alpha\text{-}Al_2O_3(s) + 3/4\ C(s) \rightarrow Al(l) + 3/4\ CO_2(g) \quad (6)$$

At 960 °C, $\Delta H^0_{1233} = +549.3$ kJ.

Additional energy is required to heat alumina and carbon from room temperature to operating temperature. The alumina fed to the cell usually is not pure α-alumina. For γ-alumina, the overall process can be represented:

$$1/2\ \gamma\text{-}Al_2O_3(s, 298) + 3/4\ C(s, 298) \rightarrow Al(l, 1233) + 3/4\ CO_2(g, 1233)$$

The enthalpy requirement for transformation of the reactants at 25 °C (298 K) to products at 960 °C (1233 K) is:

$$\Delta H_{r(35)} = \Delta H^0_{r1233} + 1/2\,(H^0_{1233} - H^0_{298})\ \gamma\text{-}Al_2O_3 + 3/4\,(H^0_{1233} - H^0_{298})\ C(s) = 606.4\ \text{kJ}$$

This value corresponds to a theoretical energy requirement of 6.25 kW h per kilogram of aluminum produced.

The reversible cell potential (decomposition voltage) for Reaction (6) can be calculated from the relation:

$$\Delta G^0_{1233} = -nFE^0_{\text{sat},\,1233} \quad (7)$$

where ΔG^0_{1233} is the Gibbs free energy change for Equation (6), 3.450×10^5 J; n is the number of electrons per unit cell reaction, i.e., 3; F is the Faraday constant, 96.487 kJ V^{-1} mol^{-1}; and $E^0_{\text{sat},1233}$ is the standard electrode potential, in volts, at 960 °C for the reaction with all reactants and products at unit activity. Substituting the appropriate values into Equation (7) and solving for the cell potential:

$$E^0_{\text{sat},\,1233} = -1.192V$$

The above decomposition potential applies to electrolyte saturated with alumina at 950 °C. The decomposition potential from melts with alumina activity less than unity can be calculated [27] from the equation:

$$E^0 = -E^0_{\text{sat}} + (RT/6F)\ \ln a_{Al_2O_3}$$

The activity of alumina in cryolite-base melts can be approximated [27] from the equation:

$$a_{Al_2O_3} = \left(c_{Al_2O_3}/c^*_{Al_2O_3}\right)^{2.77}$$

where $c_{Al_2O_3}$ is the concentration of alumina in the electrolyte, in wt %, and $c*_{Al_2O_3}$ is the saturation concentration of alumina, in wt %.

4.5. Alternate Processes

Although the Hall–Héroult process has gained industrial dominance, it has several inherent disadvantages. The most serious are the large capital investment required and the high consumption of costly electrical power. There are also the costs of the Bayer alumina refining plant and of the carbon anode plant. Many of the aluminum-producing countries must import alumina or bauxite. The supply of petroleum coke is limited. These deficiencies have spurred research to find alternate processes.

The earliest commercial process for producing aluminum was sodiothermic reduction of aluminum halides. Reduction of aluminum chloride by manganese has been investigated [41]. However, neither can compete with the Hall–Héroult process. Many attempts have been made at direct carbothermic reduction of alumina but these have resulted in very low yields, owing to the formation of solid aluminum carbide, aluminum suboxide vapor, and aluminum vapor that reacts with carbon monoxide as the temperature drops on the way from the furnace. Yields as high as 67 % can be obtained by staging the reactions to produce aluminum carbide at

1930 – 2030 °C, which then reacts with alumina to produce aluminum and carbon monoxide at 2030 – 2130 °C [42].

Better yields result from adding to the furnace a metal (or a metal oxide that is subsequently reduced to a metal), such as iron, silicon, or copper, to alloy with the aluminum and lower its vapor pressure. Of course it is then necessary to extract the aluminum from the alloy. In principle this can be accomplished by electrolytic refining, by fractional crystallization, or by monohalide distillation. In the latter process the aluminum extraction takes place at 1000 – 1400 °C:

$$AlCl_3 + 2\,Al(alloy) \rightarrow 3\,AlCl(g)$$

The AlCl gas is transported to a cooler zone, 600 – 800 °C, where pure aluminum is formed:

$$3\,AlCl(g) \rightarrow 2\,Al(pure) + AlCl_3$$

These combined processes to date have proved noncompetitive. Selective solution of aluminum from the alloy by using a volatile metal, such as mercury, lead, bismuth, cadmium, magnesium, or zinc, has been investigated. Following extraction, the volatile metal is distilled, leaving pure aluminum. If $FeAl_3$, $TiAl_3$, or Al_4C_3 is formed, neither electrolysis nor volatile metal extraction will remove the aluminum from the compound.

The aluminum vapor pressure can be lowered also by alloying the aluminum with aluminum carbide. Over 40 wt % aluminum carbide is soluble in aluminum at 2200 °C [43]. This observation led to a process in which an alloy of aluminum and aluminum carbide was produced at 2400 °C. When this alloy was tapped from the furnace and allowed to cool slowly, the aluminum carbide crystallized into an open lattice, the interstices of which were filled with pure aluminum. Pure aluminum was then removed either by leaching with molten chloride fluxes or by vacuum distillation. The aluminum carbide residue was recycled to the arc furnace. Alternately, the aluminum carbide could be distilled destructively above 2200 °C to produce aluminum and a residue of pure graphite.

In a joint project with the U.S. Department of Energy concluded in 1983, Alcoa investigated producing aluminum-silicon alloy carbothermally in a blast furnace. The required high temperature was obtained by using a pure oxygen blast. Using a low-pressure blast furnace to produce an aluminum-silicon alloy was found to be infeasible because of severe bridging and interruption of the burden movement caused by total reflux of Al, Al_2O, and SiO vapors [44], [45]. Addition of iron improved operation but required an improved technique for extracting the aluminum from the dilute aluminum alloy. An alloy having higher aluminum content could be obtained if a significant portion of the process energy was supplied by electrical power [46]. Japanese researchers are continuing to explore the aluminum blast furnace concept aiming for a low-silicon, high-iron alloy [47]. This improves the blast furnace efficiency but complicates extraction of aluminum from the alloy. They propose to overcome this difficulty by extracting the aluminum with lead [48].

In 1976 Alcoa described a smelting process wherein aluminum chloride, dissolved in a molten sodium chloride-lithium chloride electrolyte, was electrolyzed in a bipolar electrode cell to produce aluminum and chlorine. The chlorine was recycled to a fluid-bed chemical reactor, where it reacted with alumina, pyrolytically coated with carbon from fuel oil, to produce aluminum chloride, carbon dioxide, and carbon monoxide. This reaction was highly exothermic. The aluminum chloride was desublimed to separate it from the gas and recycled to the cell to produce more aluminum and chlorine. This process required 30 % less electrical power than their best Hall–Héroult cells. Because the entire process is a closed system, it is also environmentally more attractive than the Hall–Héroult process. Problems with the chemical plant and low demand for aluminum caused the pilot plant to be shut down temporarily in 1982. Research on the plant was continuing in 1984.

5. Producing High-Purity Aluminum

The Hall–Héroult process has produced aluminum with a purity as great as 99.95 %. Other techniques, such as electrolytic refining or fractional crystallization, are required to produce purer metal. Alcoa developed a three-layer electrolytic aluminum-refining cell in the 1920s. Copper was added to the bottom layer of impure aluminum to increase its density above that

of the fused salt electrolyte. The electrolyte contained 25 – 30 % sodium fluoride, 30 – 38 % aluminum fluoride, and 30 – 38 % barium fluoride to increase the electrolyte's density so that pure aluminum would float to the top. Electric current entered the anode alloy through carbon or graphite blocks at the bottom of the cell and left through graphite electrodes dipping into the high-purity aluminum on top. Aluminum was transported preferentially. Metals more difficult to oxidize than aluminum remained in the anode or alloy layer, and metals more difficult to reduce than aluminum remained in the electrolyte. A ledge of frozen electrolyte on the carbon sidewalls prevented electrical short circuiting between the floating pure aluminum layer and the carbon wall. The cell operated at 950 – 1000 °C and produced 99.98 % pure metal.

In 1932 the Pechiney Company in France operated a cell using a fluoride-chloride electrolyte and nonconducting magnesia brick sidewalls. The electrolyte consisted of 17 % sodium fluoride, 23 % aluminum fluoride, and 60 % barium chloride. The cell operated at 750 °C and produced 99.995 % pure aluminum. An all-fluoride electrolyte (18 % sodium fluoride, 48 % aluminum fluoride, 16 % calcium fluoride, 18 % barium fluoride) also can be used in magnesia-lined cells. Modern electrolytic refining cells (Fig. 11) add a segregation sump [49]. The sump, normally operated at least 30 °C cooler than the aluminum alloy anode, serves as a charging port for aluminum and permits impurity removal. As impurities concentrate in the bottom layer, saturation is reached and crystals form in the cooler sump area, where they can be removed. This procedure greatly extends the operating life of the cell.

Fractional crystallization also is used commercially to refine aluminum. As aluminum freezes most impurities preferentially concentrate in either the liquid or the solid. A molten zone is moved along an aluminum bar in zone refining. Impurities that lower the melting point of aluminum concentrate at one end of the bar, whereas impurities that raise the melting point concentrate at the other end. After several passes the ends are removed, leaving a middle portion of high-purity aluminum.

Super-purity aluminum is produced by another fractional crystallization process [50]. In the first step, peritectic elements are removed

from molten aluminum by reacting them with boron to form borides, which are precipitated and settled before the metal is transferred to a second furnace. Here the surface of molten aluminum is cooled with forced air, causing metal to crystallize. When the furnace is nearly filled with crystals, the remaining impure aluminum is drained. Then the crystals are remelted to yield very pure metal. Aluminum of purity higher than 99.995 % has been produced from 99.9 % pure smelting-grade aluminum by this process.

6. Aluminum Casting: Remelt Ingot

Metal tapped from the Hall–Héroult cell may be treated in one of several ways. First, it may be transported in the molten state to a holding furnace, where, along with solid scrap, it is alloyed, fluxed, filtered, and cast into a form suitable for fabrication by rolling, forging, etc., or for remelting by a foundry. It may be transported further (over distances up to 200 km) on trucks, equipped with well-insulated containers to prevent freezing, to a foundry where it is alloyed and used to make shaped castings. Both these methods of utilizing the molten metal are favored because energy required for remelting is conserved.

Alternatively, where ingot casting facilities or foundries are not nearby, metal is cast using cast iron molds into "primary" ingots for remelting. Generally, these unalloyed remelt ingots come as stackable 22-, 340-, or 680-kg ingots. Casting machines, such as the one illustrated in Figure 12, are often fully automated, with production rates of up to 20000 kg/h. An important con-

sideration is metal transfer from the ladle to the mold, which must be as quiescent as possible in order to minimize oxide contamination. Unalloyed ingot is sold in various purity grades, such as P 0506 or P 1520, depending on the maximum Si and Fe levels; e.g., P 0506 is aluminum with 0.05 % Si and 0.06 % Fe maximum.

Figure 12. Casting machine for the production of open-mold remelt ingot (courtesy Gautschi Electrofours SA)

The larger sizes of unalloyed remelt ingot may be cast on semicontinuous DC (direct chill) casting equipment (→ Aluminum Alloys, Chap. 3.2.) with a "T" cross section for ease of handling and stacking. This ingot usually is cut into lengths weighing approximately 340 kg.

Primary metal producers also make remelt ingot, which is prealloyed for the foundry industry. This is known as foundry ingot and generally is alloyed so that its composition lies within the limits of the alloy desired in the final shaped casting (→ Aluminum Alloys). Foundry ingot may be cast into open molds or continuously cast, cut to length, and stacked (Fig. 13). The most common masses for this ingot, which is remelted in furnaces smaller than those used by wrought alloy producers, are approximately 14 kg and 22 kg. The general practice, where applicable, is to premodify and grain refine this foundry ingot. Also the molten metal is filtered and fluxed in a manner similar to that employed for wrought alloy ingot in order to insure optimum metal quality for the foundry user.

Continuously cast "T" section bar (left); Open-mold foundry ingot (right)

7. Environmental Protection

In the primary production of aluminum there are three principal areas of environmental concern: air emissions, wastewater discharges, and solid waste. In the early years of the aluminum industry, most of the effort was directed toward controlling fluoride emission from the cells. The technology for fluoride control is now well established throughout the industry. Other significant air emission sources exist in the anode production process.

Wastewater effluent usually is not a major problem, except in those plants where wet processes are still used to scrub the air emissions from the cells and anode baking furnaces.

Cathode linings in aluminum cells are removed when lining failure occurs and large amounts of this material, called spent pot lining, must be discarded. Historically, spent pot lining has been stockpiled or used as landfill. However, the aluminum industry still needs to find disposal methods that also can provide for the recovery of raw materials.

7.1. Air Emission

Cell Room Emission. Atmospheric emissions produced by an aluminum cell consist of particulate and gaseous fluoride (predominately HF), alumina, carbon dust, sulfur dioxide, carbon dioxide, and carbon monoxide. Typical values for total fluorides generated by the cell related to aluminum production range from 20 to 30 kg/t. Approximately the same amounts of alumina and carbon dusts also are produced. Sulfur dioxide varies according to the sulfur

content of the coke used to prepare the anodes, whereas carbon monoxide emissions generally are less than 30×10^{-6} parts by volume.

Control of Cell Emissions. To control cell emissions, each cell is equipped with a closely fitted hood to collect the evolved gases, which are then ducted to pollution-control equipment. After air dilution the cell gas temperature ranges from 85 to 125 °C, depending on the ambient temperature. Both wet and dry systems are employed to treat cell gas. Some of the older smelters use a combination of electrostatic precipitators for solids removal following by spray towers for removing hydrogen fluoride gas and some sulfur dioxide. Wet precipitators also are quite effective for collecting both gaseous and particulate fluorides; some sulfur dioxide also may be collected by wet precipitators.

Because of inherent disadvantages in wet systems, not the least of which is potential water pollution, new smelters employ *dry scrubbers* for controlling cell emission. A dry scrubber uses either a fluidized bed or direct injection of metal-grade alumina into the gas stream to remove the hydrogen fluoride gas by sorption. The larger the specific surface area of the alumina, the greater is its sorptive capacity for hydrogen fluoride.

The alumina usually is recovered from the gas stream by a fabric filter, which also removes the other entrained particulate species. Dry scrubber efficiencies are generally greater than 98 % for both the gaseous fluoride and the particulate matter. Dry scrubbers are considered to be state of the art control technology. The aluminum fluoride that is recycled to the cells represents a significant material recovery value.

Emissions from Anode Preparation. In the production of anodes, coke dust and pitch fumes are generated at the mixers and at the anode forming equipment. These emissions must be exhausted from the work area for worker protection.

Pitch fumes, coke dusts, and fluorides are the chief pollutants in the waste gases from the anode baking furnaces. In most countries, limits are established for aluminum fluorides (0.05 kg per ton of aluminum) and particulate (dust) emissions, or opacity limits are set in lieu of particulate limitations.

Control Systems for Anode Baking Furnaces. The control systems for the baking furnace emissionsare similar to those described for the cell, with both wet and dry systems being utilized. Fluidized alumina beds and alumina injection systems are used to control gaseous fluorides and hydrocarbons from most new furnaces. A major difference, however, is the need to cool the baking furnace gas in order to condense the hydrocarbons so that they can be extracted by the dusts on the bag filter.

7.2. Wastewater Discharge

Fume Collection Systems. Wastewater generation has been reduced drastically with the development of dry systems for controlling emissions. Some older facilities still rely on wet collection devices, which result in a wastewater stream contaminated with acid, fluoride, and organic material. Conventional treatment involves addition of lime and prolonged retention times (12 h to several days) for neutralization and removal of the calcium fluoride precipitate and a significant portion of the dissolved organic compounds, e.g., benz[*a*]anthracene, benzofluoranthene, benzo[*a*]pyrene, chrysene, and phenanthrene. At least 98 % of these can be removed by biologic treatment in a facultative lagoon that employs aerobic as well as anaerobic bacteria. Partial decomposition of the organic material occurs in the anaerobic bottom layer, whereas the aerobic bacteria present in the upper levels complete the degradation process. Other organic removal mechanisms in the facultative lagoon include skimming, adsorption, and sedimentation.

Sodium hydroxide and alum are used in place of lime for fluoride removal at some plants. This treatment creates a fluoride sludge that, after drying, can be used as a cryolite replacement in the aluminum cell.

Pot Wash Water. After failure of a cathode lining, most of the metal and bath are tapped from the cell and materials remaining within the shell are removed. This "pot digging" operation can be done either "wet" or "dry". In "wet digging," water is applied to the pot to shock thermally and to fracture the bath, metal, and lining material that remain in the pot.

The best approach to handling pot wash water is to minimize the amount of wastewater generated through good management practices during the soaking operation. Excess water is collected in a sump and used as makeup to the next pot brought in for relining. Under no circumstances is this water discharged to a receiving stream because it may contain cyanide (10 – 200 mg/L total CN^-) and fluoride (100 – 600 mg/L).

Plant Runoff. Although aluminum smelting is a dry process, some water is required for services, such as boiler makeup, various equipment cooling needs, and area wash water. A major source of wastewater at a smelting plant is stormwater runoff. Although intermittent, the contaminant loading is significant if efforts are not made to keep courtyards relatively free of dust and to protect spent pot linings from the elements. To minimize the environmental impact of storm water and the other miscellaneous flows, many primary aluminum plants direct their storm sewers through an equalization/holding basin before discharge. This basin is designed to remove suspended solids and floating matter (oil and grease) and also to equalize the fluoride concentration.

7.3. Solid Waste

The material removed from the pot after liner failure is referred to as spent pot lining and represents the largest volume of solid waste associated with the smelting process. Over 3×10^5 t of spent pot linings were estimated to have been generated in 1983 by the worldwide aluminum industry.

The Environmental Protection Agency in the United States initially classified spent pot lining as a hazardous waste because of its cyanide content. Pot lining subsequently was removed from the hazardous waste list pending further studies.

Present disposal/management practices include "temporary" storage in curbed, roofed, protected areas to minimize leachate generation, and burial in landfills lined with impervious materials to prevent contamination of the surrounding environment. These procedures are costly because of the large volumes involved. Because of the carbon and fluoride content of the solid waste, research is directed toward recovering or utilizing these valuable components. Potential applications for spent pot lining include recovery and reuse of the fluoride and carbon constituents, use as a flux material in the steel industry, use as a supplemental fuel by cement manufacturers, and use as fuel in fluidized-bed boilers.

7.4. Regulatory Requirements

Regulatory limits throughout the world have been summarized in an International Primary Aluminium Institute publication [51]. In the United States new carbon bake furnace emissions are limited to 20 % opacity and the total fluoride as a function of aluminum produced is set at 0.05 kg/t. New potroom emissions are limited to 10 % opacity and 0.95 kg/t total fluoride. The effluent limitation guidelines are presently being revised with emphasis on control of toxic pollutants.

8. Economic Aspects

The geographic distribution of primary aluminum production has undergone important changes in the past decade or so. Table 6 shows production figures in 1972 and 1982 for several major countries and the shares of the Western World they represent.

Table 6. Primary aluminum production for selected countries and share of Western World total ($\times 10^3$ t/a)

	1972		1982	
	Prod.	%	Prod.	%
United States	3740	41	3270	31
Canada	920	10	1070	10
Japan	1009	11	350	3
Norway	558	6	640	6
West Germany	444	5	710	7
France	394	4	380	4
Western World	9206	100	10500	100

The decline in production in the United States and Japan is significant. The change that is taking place is largely a result of the rapid rise in energy costs that began with the oil crises of 1973 and 1979 – 1980. The cost of power has become the critical element in the economic viability of primary aluminum facilities. Table 7 shows the estimated percentage of total costs for major cost

components in the production of aluminum for pre- and post-oil embargo periods.

Table 7. Cost breakdown for primary aluminum production for an average smelter in the Western World (%)

	Pre-1973	Post-1980
Alumina	35	30
Power	15	30
Labor	20	15
Miscellaneous	30	25
Total	100	100

Prior to the first oil embargo in 1973, the range of variable costs to produce aluminum was narrow among all smelters. Since then, the range of costs has remained small except for power. The cost of oil- and gas-based electricity escalated to the extent that some smelters were paying 20 times the rate per kilowatt hour of the lowest cost smelters. This is the reason that the Japanese industry has reduced its primary capacity from its peak of 1.6×10^6 t/a to a 1983 level of 0.7×10^6 t/a. Some United States capacity, particularly natural-gas powered smelters in the southwest, has been permanently closed, and further shutdowns are likely.

Largely because of escalating power costs, geographic dispersion of primary capacity is occurring in the Western World. From the end of 1972 to the end of 1982, capacity more than doubled in Africa, more than quadrupled in Latin America, and decreased by 40 % in East Asia. Regional capacities, from data supplied by the International Primary Aluminium Institute for 1972 and estimated for 1982, are given in Table 8.

Table 8. Year-end primary aluminum production capacity ($\times10^3$ t/a)

	1972	1982
Africa	254	615
North America	5430	6135
Latin America	228	1065
Eastern Asia	1323	790
Southern Asia	354	843
Western Europe	3056	4200
Oceania	345	700
Total	10990	14348

Much of the new capacity built in the past decade is nonintegrated; that is, the facility is not tied directly to bauxite or alumina production and no fabricating operations are associated with the smelting facility. This helped promote the trading of aluminum on the London Metal Exchange, and on the aluminum contract on the New York Commodities Exchange.

The creation of a terminal market has accelerated the development of unalloyed aluminum as a commodity product, with the price volatility that commodity status entails.

9. Toxicology and Occupational Health

The bulk of the epidemiological literature confirms that, in humans, aluminum and its compounds exhibit a very low order of toxicity [52–55]. Whether taken into the body by ingestion or inhalation, very little aluminum finds its way into body tissues. The aluminum content of the adult human body is 50 – 150 mg [56], [57]. Because of its ubiquitous nature, aluminum also is found in many foods that make up our normal diets. The amount ingested ranges from as little as 1 to >100 mg/d [58]. The use of aluminum cooking utensils and food packaging does not contribute significantly to the amount that is ingested normally [59], [60]. Regardless of the route of intake, most of the aluminum is eliminated through the gastrointestinal tract.

For many years aluminum, in the form of $Al(OH)_3$, was used widely at high dosages as an antacid, with no apparent ill effects. Although aluminum is known to have neurotoxic properties [61–64], it does not exhibit these properties in normal human beings because it is eliminated readily from the body. On the other hand, for those who have impaired renal function, it can be neurotoxic. There are strong implications that aluminum is a major factor in dialysis encephalopathy, an ultimately fatal condition that sometimes occurs in those with renal failure who undergo dialysis. The major symptoms are speech difficulties, dementia, and seizures. Traces of aluminum in the water used for the preparation of dialysis fluid can accumulate in the patient because the impaired kidneys are unable to eliminate it.

Those with renal failure, whose aluminum serum levels are elevated as a result of dialysis or the oral administration of aluminum compounds, are also at special risk of developing osteomalacia, a softening of the bone that re-

sults in pain and an increased incidence of bone fractures.

Although aluminum has been implicated as being associated with Alzheimer's disease, a condition of premature senility [65], [66], the evidence to date suggests that it is not causal. Aluminum's role, if it plays a part at all, appears to be secondary to some unknown primary agent [67], [68].

With a few exceptions, most of the literature dealing with *inhalation exposures* of humans and experimental animals to aluminum and its compounds shows these materials to be relatively innocuous. However, there are reports contending that aluminum and aluminum oxide dusts are fibrogenic. A critical examination of the original references reveals that the evidence for this contention is inconsistent and mitigated by compounding variables.

Cases of pulmonary fibrosis attributed to aluminum powder exposures as reported in the literature [69–74] are equivocal. In most of these instances, environmental conditions were poor, dust exposures were extremely high, materials other than aluminum were known or suspected to be present, smoking and work histories of those affected were not given, and the types of fibrosis seen were not always consistent. Of these cases, 47 in all, one was reported from Japan and the remainder from Europe. No case has been reported from North America, even though similar production operations were conducted there over the same period of time.

A study of 125 employees involved in a powder stamping operation in the United States failed to show any evidence of fibrosis [75]. Their exposure times ranged from 6 to 23 years (mean average of 12). Furthermore, a therapeutic administration of heavy doses of aluminum powder, by inhalation, to silicotics over a period of 30 – 50 weeks showed no detrimental effects to the patients [75]. A report in 1973 indicated that the failure of inhaled metallic aluminum powder to cause pulmonary fibrosis in experimental animals "parallels the clinical experience in the United States but it leaves unexplained the occurrence of fatal pulmonary fibrosis in England from the inhalation of pyro aluminum powder" [76]. Worldwide, no case has been reported since 1962.

In 1947 cases of pulmonary fibrosis were attributed to aluminum oxide fume exposure [77]. Subsequent investigation demonstrated the presence of silica in these fumes [78]. Silica generally is accepted today as the principal cause.

The American Conference of Governmental Industrial Hygienists continues to recommend a 10 mg/m^3 TLV for aluminum metal and alumina dust, the same as for nuisance or biologically inert materials [79]. They also have established a lower limit applicable to aluminum pyro powders and aluminum welding fumes, 5 mg/m^3. This concentration is consistent with limits for nuisance materials with particle sizes in the respirable range. Health regulatory agencies in Australia, the Federal Republic of Germany, the Netherlands, Sweden, and many other countries consider aluminum oxide dusts to be nuisance particulates [80]. No MAK values have been set.

1. Introduction

Most primary aluminum is used for metallurgical purposes: aluminum-based alloy castings and wrought products, alloying additions to metals, coatings on metals to prevent corrosion and oxidation, and reducing agents to produce metals from their oxides and fluorides. Of these metallurgical uses, aluminum-based alloy castings and wrought products make up about 85 – 90 % of aluminum shipments in the United States.

A comprehensive summary of the properties, production, fabrication, and use of aluminum alloys was published in 1967 [1–3]. Summaries of

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a01_481

properties and physical metallurgy are given in [4], [5]. Commercial aluminum alloy products are described in [6], [8]. Commercial alloys of other metals that contain aluminum are given in [7], [8, pp. 237 ff.], [9]. Heat treatment [10], surface treatment [11], and joining [12] of aluminum alloys have been described.

2. Metallurgy of Aluminum Alloys

The properties of aluminum alloys depend on the metallurgical structure, which in turn depends on composition, solidification processes, and post-solidification thermal and deformation processing [1], [4], [5].

2.1. Composition

Many alloying elements are added to aluminum to enhance its properties (Table 1) [13], [14]. The major elements increasing strength are copper (see Fig. 21), magnesium (Fig. 1), manganese (Fig. 2), silicon (Fig. 3), and zinc (Fig. 4). All these have maximum solid solubility limits in excess of 1.5 % (Table 2) [1, pp. 362 – 3]. Elements with lower solubilities, e.g., chromium (Fig. 5), zirconium, and titanium, are added to certain alloys to aid in controlling aspects of metallurgical structure, e.g., as-cast grain size and the nature of recrystallization, and thus to affect the characteristics of the alloys. Of the elements commonly added, copper, magnesium, silicon, and zinc have high diffusion coefficients; other elements diffuse only slowly [1, p. 118].

Table 1. Elements in commercial aluminum alloys: maximum specified, wt %

Element	Wrought alloys	Casting alloys
Ag	–	1.0
Be	–	0.3
Bi	0.7	–
Co	1.9	0.3
Cr	0.40	0.6
Cu	6.8	11.0
Fe	2.0	2.0
Mg	5.6	10.6
Mn	1.8	0.8
Ni	2.3	3.0
O	0.5	–
Pb	0.7	0.25

Si	13.5	23.0
Sn	22.0	7.0
Ti	0.2	0.35
V	0.15	0.2
Zn	8.7	8.0
Zr	0.3	0.3

Commercial alloys are usually multicomponent systems, and the phase diagrams are frequently complex. One important precipitation-hardening system, Al – Mg – Si, is shown in Figure 6 (page after next) in the form of contour maps representing the solvus, solidus, and liquidus surfaces.

The composition of a specific alloy is often written as, e.g., Al – 5.1 Mg – 0.79 Mn – 0.11 Cr (Aluminum Association Number 5456), meaning an alloy consisting of 5.1 wt % Mg, 0.79 wt % Mn, 0.11 wt % Cr, and the rest aluminum and the usual impurities.

2.2. Solidification and Cast Structure

2.2.1. Grain Size and Dendrite Arm Spacing

The transformation from the liquid to the solid state in aluminum alloys is assisted by heterogeneous nucleation. Cast grain size is controlled by adding potent grain-refining nuclei to the melt to minimize the amount of undercooling and maximize the number of nucleation sites. Once nucleation has occurred, growth continues under commercial casting conditions with a dendritic structure, illustrated in Figure 7. An important characteristic of a dendrite is the dendrite arm spacing (DAS) or cell size. The DAS is related to the cooling rate during freezing, as shown in Figure 8 [15]. This relationship is described by the equation

$$d = kQ^{-n}$$

where d is the DAS in µm, k is a constant with a value of 35, Q is the cooling rate in K/s, and n is an exponent with a value of 0.33.

In wrought alloy ingot 500 mm thick, the DAS varies from about 15 µm close to the surface to 80 µm at the center. Roll-cast strip (6 mm thick) has a DAS ranging from 5 to 12 µm. In contrast, the grain size of grain-refined direct chill cast ingot ranges from 50 to 300 µm, depends mainly on nucleation and growth conditions, and is not strongly affected by cooling rate.

Figure 7. Typical dendritic growth forms: photomicrograph of electropolished as-cast 2124 alloy taken under polarized light

Figure 8. Dendrite cell size (DAS) as a function of cooling rate

2.2.2. Segregation

In most aluminum alloys the solute (or alloying element) is less soluble in the solid phase than in the liquid phase (see Fig. 9), and addition of solute lowers the freezing point. As a consequence, when an aluminum alloy solidifies, solute is rejected at the solid – liquid interface, resulting in (1) solute buildup in the liquid ahead of the freezing front and (2) breakdown of the planar solidification interface. The former gives rise to segregation in the cast structure, commonly called coring, and is directly responsible for the dendritic growth form. Segregation occurs on both microscale and macroscale. *Microsegregation* is that which forms on the scale of the dendrite arm spacing, whereas *macrosegregation* describes solute differences over distances of several centimeters.

Figure 9. Al – Cu phase diagram (up to 15 wt % Cu)

Microsegregation is best described in terms of the solute distribution between two dendrite arms. A typical solute distribution profile in a direct chill cast ingot is illustrated in Figure 10. (The copper at different locations within the volume element was determined by electron-probe microanalysis.) If the solidifying metal between two dendrite arms is considered a closed volume element with no mass flow of liquid in or out (a reasonable first approximation), then the redistribution that takes place can be described adequately by the Scheil equation:

$$c_s = c_0 k\,(1-)\,f_s^{k-1}$$

where c_s is the composition of the solid at fraction solid f_s, c_0 is the original alloy composition, and k is the equilibrium partition ratio (see Fig. 9) [16].

Figure 10. Copper distribution between dendrite arms in direct chill (D.C.) cast 2124 alloy
– – – – – Analysis path

Macrosegregation arises because of the flow of segregated liquid from one area of a solidifying casting to another. A typical solute distribution across a 600-mm-thick commercial direct chill ingot of 2024 alloy is illustrated in Figure 11. The driving forces for macrosegregation are (1) shrinkage contraction that accompanies the transformation of liquid to solid, (2) density differences in the liquid phase, and (3) convective stirring that arises from the temperature gradient across the crater of a solidifying ingot.

Figure 11. Variation in copper concentration across a 600-mm-thick direct chill (D.C.) cast ingot of Al – Cu – Mg alloy

Macrosegregation has been described with some success by analogy to fluid flow through a porous medium, i.e., with D'Arcy's law

$$v = -\frac{k}{\eta\varphi_l}\left(\nabla P + \varrho_l g\right)$$

where v is the mean interdendritic flow velocity, k is a constant for the permeability of the medium, P is pressure, g is the acceleration due to gravity, η is viscosity, φ_l is the volume fraction of liquid, and ϱ_l is the liquid density [16].

2.2.3. Porosity

Porosity in aluminum ingot and castings arises from two principal sources: (1) shrinkage contraction and (2) the rejection of dissolved gas on freezing. The characteristic feature of *shrinkage porosity,* which arises from inadequate feeding of the solidifying casting with molten metal, is its angularity. In contrast, *gas porosity* is more or less spherical. All commercial aluminum castings contain some gas above the solid-state equilibrium level, and all shrinkage porosity contains some gas.

Hydrogen is the only gas that is significantly soluble in aluminum. At the melting point of aluminum, hydrogen is 20 times more soluble in the liquid than in the solid (Fig. 12) [17]. Even when the hydrogen level is reduced below the equilibrium concentration in molten aluminum by fluxing, the low solubility of the gas in the solid causes hydrogen to go into the remaining liquid. When the internal gas pressure exceeds atmospheric pressure, a bubble of gas can form. For a given gas content, the amount of porosity is increased by increased alloy freezing range and decreased cooling rate (Fig. 13) [18].

Figure 12. Solubility of hydrogen at 0.1 MPa (1 bar) in aluminum

There is no measurable porosity, regardless of the conditions, if the hydrogen content is below about 0.10 mL per 100 g. At these low hydrogen contents the internal pressure in the liquid cannot exceed atmospheric pressure. Instead, the gas in excess of the solid-state equilibrium level at the freezing point coprecipitates with vacancies behind the solid – liquid freezing front. The pores are extremely small (1 µm) and contain hydrogen at pressures of about 20 bar (2 MPa).

Figure 13. Relationship between porosity and hydrogen content in semicontinuously direct chill (D.C.) cast ingot a) Thick ingot; b) Thin ingot; c) 99.2 % Al; d) 99.99 % Al Both thick (a) and thin (b) ingots are long freezing range alloy 7xxx.

This porosity is not readily discernible in the cast structure, but the pores expand considerably on heating. The terms primary and secondary porosity are used to distinguish macroscopic and microscopic forms of hydrogen porosity [19].

2.2.4. Nonmetallic Inclusions

There are three major types of solid inclusions in aluminum alloys: (1) oxides, (2) borides, and (3) carbides.

Molten aluminum reacts readily with moisture in the atmosphere. The resulting aluminum *oxide* film is generally quite coherent and inhibits further growth. But whenever the molten metal surface is disturbed, e.g., during the mixing in of alloying elements or tapping from the furnace to a transfer trough, a fresh oxide layer is formed immediately on the newly exposed surface. Therefore, oxides found in cast structures are usually filmlike. An exception is spinel, $MgAl_2O_4$, which grows on Al – Mg alloy melts when the first-formed MgO film crystallizes and "breakaway" oxidation ensues. Spinel is particulate.

Borides originate from the presence of the transition elements Zr, V, and Ti along with boron in the Hall – Héroult cell. These impurities, which come from the alumina feed and anode material, are somewhat soluble at 950 °C, but transition metal borides precipitate as the metal cools to furnace temperature (750 °C). Another source of boride inclusions, but usually of much smaller size (0.5 to 3 µm), is the Al – Ti – B master alloy used for grain refining.

Carbides, generally in the form of Al_4C_3, also arise from the cell metal. At 950 °C carbon has a solubility of 50 ppm in molten aluminum. As the metal cools, the solubility drops to 1 ppm, with the resultant precipitation of carbide particulate.

2.3. Thermal and Mechanical Processes

2.3.1. Preheating

Ingot to be fabricated to wrought products is usually preheated or homogenized [4, Chap. 5]. This treatment, often near the melting temperature, lasts a few hours to a few days. Preheating alleviates microsegregation (coring and soluble grain boundary segregation) by diffusion and makes the ingot more amenable to hot deformation. Preheating followed by slow cooling is used to bring certain elements, e.g., manganese, into solid solution and then precipitate them into a more desirable form, usually very fine dispersoids, for control of recrystallization, formability, toughness, finishing, etc. During homogenization, secondary porosity increases in size, but the porosity will eventually disappear, collapsing under the force of surface tension, if the conditions in the furnace are favorable for the loss of hydrogen from the ingot.

During solidification, insoluble intermetallics, such as $FeAl_3$, precipitate with an angular geometry. During homogenizing heat treatments this type of precipitate becomes less angular, and the fabricability of the ingot is enhanced.

There is sufficient residual stress in a direct chill cast ingot to cause recrystallization and grain growth in alloys containing no insoluble particles, as shown in Figure 14.

Figure 14. Abnormal grain growth in a direct chill (D.C.) cast 5252 alloy ingot homogenized at 565 °C for 4 h (0.09X) Aqua regia etch

2.3.2. Non-Heat-Treatable Alloy Processes

The non-heat-treatable alloys are strengthened by dispersion, solid solution, and work hardening [4, Chap. 4]. The common alloy systems of this type are unalloyed aluminum containing controlled levels of impurities (mostly Fe and Si), Al – Mn, and Al – Mg. Strength increases with increasing content of the alloying component (Fig. 15). Magnesium is more soluble in aluminum than Fe and Si or Mn, and Al – Mg alloys are capable of reaching the highest strengths. Strength increases also when the dislocation density is increased by deformation: the increase is determined by the composition and the amount and temperature of deformation. Figure 16 shows for three alloys, how the yield strengths are increased and the elongations decreased by rolling at room temperature.

The strain induced by deformation can be reduced by heating; the rate of reduction is determined by alloy, amount of strain, temperature, and time. Figure 17 shows the effects of heating time and temperature on the yield strength and elongation of alloy 1100 given about 75 % cold reduction (H18 temper). The effect of lower strains (H12 and H14) at 204 °C is illustrated in Figure 18. The initial drop in strength is caused by recovery processes involving changes in dislocation structure. Higher temperatures and longer times increase the degree of recrystallization and thus the ductility, and decrease strength, until full annealing is achieved. Heating to achieve properties between strain hardened and fully annealed is known as partial annealing.

Figure 15. Effect of magnesium content on tensile properties

Figure 16. Effect of cold rolling on yield strength and elongation of three alloys

Figure 17. Effect of heating time and temperature on yield strength and elongation of 1100-H18
The gage length over which the elongation is measured is four times the diameter of the specimen (4D)

Figure 18. Effect of strain (H12, H14, H18) and heating time at 204 °C on yield strength and elongation of 1100 alloy

Strain-hardened Al – Mg alloys recover at room temperature, the rate of recovery increasing with Mg content and amount of original strain. This long-term recovery can be prevented by stabilizing at moderate temperatures. Figure 19 illustrates the effects of the recovery process and stabilization on an alloy cold worked on four strain levels.

Figure 19. Recovery at room temperature of strain-hardened and stabilized (8 h, 143 °C) Al – 2.43 Mg – 0.25 Cr alloy sheet

2.3.3. Heat-Treatable Alloy Processes

Heat-treatable aluminum alloys depend on precipitation from supersaturated solid solution to develop high strength [4, Chap. 5], [10, pp. 675 – 718]. The basic requirements for alloying elements are high solid solubility at elevated temperatures, low solubility at room and moderate temperatures, and precipitates that strain the lattice. The typical precipitation sequence is

supersaturated solid solution → Guinier – Preston zones → metastable phases → stable phases

Examples of the sequence are given in Table 3 for several systems [20–22]. The major commercial heat-treatable alloy systems are Al – Cu, Al – Cu – Mg, Al – Cu – Si – Mg, Al – Si – Mg – Cu, Al – Mg – Si – Cu, Al – Mg – Si, Al – Zn – Mg, and Al – Zn – Mg – Cu. Alloys containing lithium, which has a solid solubility limit of 4 wt % at 600 °C, have been the subject of extensive research and have become commercial in limited applications.

Table 3. Aluminum alloy precipitation sequences

Al – Cu	S.S.$\alpha \rightarrow$GP[1]$\rightarrow$GP[2] or $\theta'' \rightarrow \theta' \rightarrow \theta(CuAl_2)$
Al – Si	S.S.$\alpha \rightarrow$Si

	S.S.$\alpha \rightarrow$G.P. zones$\rightarrow$T$' \rightarrow$T$(Mg_3Zn_3Al_2)$
Al – Li	S.S.$\alpha \rightarrow \delta'(Al_3Li) \rightarrow \delta(AlLi)$
Al – Li – Cu	S.S.$\alpha \rightarrow$G.P. zones$\rightarrow \theta'' \rightarrow \theta' \rightarrow \theta(Al_2Cu) \rightarrow T_1(Al_2CuLi)$
Al – Li – Mg	S.S.$\alpha \rightarrow \delta'(Al_3Li) \rightarrow Al_2LiMg$

As the precipitation sequence proceeds, lattice strain and strength increase, whereas ductility decreases and then increases. The strength can increase at room temperature (natural aging) or at moderate temperatures (artificial aging or precipitation heat treatment). Aging past peak strength is known as overaging and for practical purposes occurs only at elevated temperatures.

The kinetics of the precipitation sequence and the magnitude of the effects on properties are determined by composition, temperature, and strain. Some effects of composition on *natural aging* are illustrated in Figure 20. The Al – Cu – Mg alloy (2024) effectively reaches peak strength after about 100 h. The Al – Mg – Si

Figure 20. Effect of natural aging time on strength and ductility of some aluminum alloys

alloy (6061) also hardens rapidly for the first 100 h, but strength continues to rise more rapidly than for the Al – Cu – Mg alloy for at least ten years. The strength of the Al – Zn – Mg – Cu alloy (7075) rises even more rapidly than that of the Al – Mg – Si alloy, with no sign of leveling. Ductilities, as indicated by elongation tests, fall slowly as strengths rise.

The classic system for studying precipitation hardening and *artificial aging* is Al – Cu. The equilibrium phase diagram (Fig. 21) shows the maximum solid solubility of 5.65 wt % at 548 °C and a solubility of less than 0.2 % at 250 °C. The aging sequence of an Al – 4 Cu alloy is illustrated in Figure 22 [23]. (Al – 4 Cu is an alloy consisting of 4 wt % Cu and the rest aluminum.) After solution heat treating above 500 °C and quenching to retain a supersaturated solid solution, artificial aging proceeds at moderately elevated temperatures as shown, with initially rising and then falling hardness. The changes in hardness are associated with the appearance of G – P (Guinier – Preston) zones and their transformation to θ' and θ.

Artificial aging accelerates the precipitation sequence; higher strengths are obtained within practical time frames. (Compare the curves in Figure 23 with the curve for 2024 in Figure 20.) The decrease in strength from *overaging* is associated with changes in metallurgical structure, resulting in more stable properties and dimensions and increased toughness and resistance to corrosion, in particular to exfoliation and stress-corrosion cracking in the Al – Zn – Mg – Cu alloys. These effects are illustrated in Figures 24 and 25 [24].

Figure 21. Aluminum – copper phase diagram (up to 10 wt % Cu)

Figure 22. Effect of aging time and temperature on hardness and structure of Al – 4 Cu alloy

Figure 23. Effect of aging temperature and time on strength and ductility of an Al – Cu – Mg alloy (2024) not cold worked between quenching and aging

Figure 24. Effect of overaging on strength and toughness of an Al – Zn – Mg – Cu – Cr alloy (7075)

Figure 25. Effect of overaging time and temperature on stress-corrosion cracking of Al – Zn – Mg – Cu – Cr alloys containing 4.5 – 7.5 % Zn, 1.5 – 3.8 % Mg, 0.75 – 2.5 % Cu, and 0.05 – 0.5 % Cr

The precipitation sequence is accelerated also by *strain* introduced after quenching. The effects of strain on natural aging and on artificial aging of an Al – Cu – Mg alloy are shown in Figures 26 and 27, respectively. The introduction of strain after artificial aging also increases strength and reduces ductility (Fig. 28).

The preceding discussion is essentially in terms of strength and ductility. However, much of the manipulation of metallurgical structure by composition, solidification rate, thermal practices, and deformation of commercial products is done to obtain an optimum combination of properties and characteristics, including strength, ductility, toughness, formability, corrosion resistance, finishing characteristics, fatigue resistance, and machinability.

3. Production Methods for Aluminum Alloys

The flow of aluminum from reduction plants to end product, as well as the important scrap loops, is shown schematically in Figure 29. Producers of mill products and castings use both primary and secondary metal to produce the intermediate products that manufacturers need to produce final products.

The production of mill products and castings begins with the melting and casting operation. Castings are made in final or near-final shapes. For mill products, ingots are cast with rectangular or circular cross section and subsequently

Figure 29. Flow of aluminum alloy products

worked down to the desired shapes. Alternate methods for producing thin sheet and foil consist of continuously casting and rolling thin wide strip. In similar processes for producing rod, bar, and wire, the alloy is continuously cast into a small bar, rolled through grooved rolls, and drawn through dies. Other processes begin with atomized powders, which subsequently are compacted and then deformed.

3.1. Melting and Metal Treatment

Aluminum and aluminum alloys are melted before conversion into castings, ingot for subsequent fabrication or remelting, particulate for chemical applications and alloying with other metals, and powders for pigments and powder metallurgy. The components of the melt may include molten metal directly from the reduction cell, primary ingot, scrap aluminum, remelted scrap ingot, and alloying elements [3, Chap. 1].

3.1.1. Impurities in the Molten Metal

The principal impurities in aluminum from the Hall – Héroult cell are listed in Table 4. The ranges are shown as a guide and are not absolute values.

Table 4. Impurities in aluminum from the Hall-Héroult cell

Impurity	Usual concentration range, %
Fe	0.06 – 0.35
Si	0.05 – 0.15
H	ca. 3×10^{-5} *
Na	0.002 – 0.004
Ca	0.002 – 0.004
Li	0.002 – 0.004
Ti, Zr	0.005 – 0.020
V, Cr	0.005 – 0.020
Al_2O_3	variable
Al_2MgO_4 (spinel)	variable
Al_4C_3	variable
TiB_2, etc.	variable

* 0.20 – 0.60 mL per 100 g Al

Hydrogen is the only gas significantly soluble in molten aluminum. It arises in the reaction of molten metal with moisture in the atmosphere, refractories, or reaction products. The standard free energy (ΔG°) for the reaction

$$3\,H_2O\,(g) + 2\,Al\,(l) \longrightarrow Al_2O_3 + 3\,H_2\,(g)$$

is high:

$$\Delta G^\circ = -979100 - 719\,T\log T + 413\,T \quad (\Delta G^\circ \text{ in J/mol})$$

The molecular hydrogen dissociates and enters the metal interstitially:

$$H_2\,(g) \rightleftharpoons 2\,H\,(soln)$$

At equilibrium:

$$K = \frac{a_H^2}{a_{H_2}} \approx \frac{c^2}{P}$$

where K is the equilibrium constant, a_H and a_{H_2} are activities, c is the concentration of dissolved gas, and P is the gas pressure. The concentration of dissolved gas is given then by

$$c = k\sqrt{P} \quad \text{where} \quad k = \sqrt{K}$$

commonly known as Sievert's law. Reaction of molten aluminum with moisture is not only the source of hydrogen but also the principal source of oxide contamination. The alkali metals and alkaline earth metals (Li, Na, and Ca) come mainly from the electrolyte in the Hall – Héroult cell and from refractories. Borides originate from impurities in the carbon anodes and alumina, whereas carbon enters into solution by dissolution of the anodes.

3.1.2. Alloying

Alloying is normally carried out in the temperature range 700 – 730 °C. The lower-melting additions, such as Zn, Mg, Cu, and Si, are made in elemental form, whereas the higher-melting point additions are made as master alloys or briquettes (Table 5).

Table 5. Aluminum master alloys and briquettes for alloying

Composition	Principal constituents
Al – 10 % Cr	$CrAl_7$
Al – 10 % Mn	$MnAl_4$ and $MnAl_6$
Al – 25 % Fe	Al_3Fe
Al – 6 % Zr	Al_3Zr
Al – 3 or 4 % B	AlB_2 and AlB_{12}, respectively
75 % Mn – Al	Al and Mn powder
75 % Cr – Al	Al and Cr powder

3.1.3. Recycling and Skim Treatment

Great emphasis is placed on the recovery of aluminum from scrap. The principal motivation is energy savings; about 20 times as much energy is needed to produce aluminum from ore as to produce the equivalent amount from scrap. Recycling of beverage cans is increasing in the United States as primary producers, beverage companies, secondary metal dealers, and civic organizations continue to open collection centers. The growth of recycling of aluminum cans in the United States is shown in Table 6 [25, p. 30].

Table 6. Aluminum can reclamation, 1986 – 1996

Year	Aluminum collected, 10^6 kg	No. of aluminum cans collected, 10^9	Percentage of aluminum cans collected
1986	550	33.3	48.7
1987	596	36.6	50.5
1988	672	42.5	54.6
1989	753	49.4	60.8
1990	863	55.0	63.6

The primary problems encountered in the recovery of aluminum from scrap are *melt loss* and *contamination.* Prevention of large losses when melting oily scrap, lightweight cans, foil, etc., requires special techniques, including melting in molten salt (NaCl or NaCl + KCl) and ablative melting, i.e., submerging the scrap below the surface of a molten aluminum charge. The principal contaminants encountered in recycled metal are silicon, iron, and titanium (from paint pigment on beverage containers). Because there are no simple methods of removing these elements from molten aluminum, scrap must be presorted before it is melted. Many foundry alloys can contain high levels of these elements, but for wrought alloys the only way to recycle scrap is to dilute the contaminants with pure metal.

The *skim* that forms on molten aluminum may be 70 – 95 % unoxidized aluminum metal, depending on the type of charge, furnace, holding temperature, alloy, and fluxing treatment. A variety of methods have been devised to recover metal from skim. Most depend on a combination of mechanical crushing, screening, and mixing in a molten salt bath to separate metal from the oxidized fraction. The salt bath is normally an eutectic mixture of NaCl and KCl with 5 – 10 % cryolite.

3.1.4. Molten Metal Treatment

Most uses of aluminum alloys demand high quality with respect to contaminants. For example, sheet for containers, plate, sheet and forgings for aircraft structures, memory disks for computers, and articles with a decorative finish, such as automotive trim, all require low levels of nonmetallic impurities. Hydrogen is particularly deleterious because it causes gas porosity in the cast ingot, possibly leading to defects such as blisters in sheet and extrusions and reduced mechanical properties in forgings and thick plate.

Even under the most favorable melting conditions, some degassing treatment is usually required prior to pouring high-quality ingot or castings. Treatment may be either batch in the furnace or continuous during transfer of the melt from the furnace to the casting unit. In the batch method the melt is purged with Ar, N_2, or Cl_2 or a mixture of Cl_2 with either of the inert gases. However, because furnace fluxing is inefficient and environmentally damaging, it is being replaced by continuous processes, which often

combine gas removal with filtration. A number of these systems are described in [26]. Figure 30 illustrates a typical bed filtration system (Alcoa 528) combined with a gas purge for hydrogen and alkali metal reduction (Alcoa 622). Figure 31 shows a successful method of filtration with a porous ceramic plate [27].

Figure 30. Molten metal fluxing and filtering system with Alcoa 622 and 528 metal treatment units

Figure 31. Filtration with a porous ceramic plate

Before the metal is cast into ingot, *grain refiner* is usually added to control the grain structure of the ingot. Reducing the as-cast grain size has a number of benefits, such as reducing the sensitivity of the metal to hot cracking during solidification, enhancing the hot workability of the ingot, and producing a wrought structure that gives a uniform appearance on etching and anodizing. Grain refinement is carried out most effectively by the addition of titanium and boron in the form of an Al – Ti – B master alloy. The master alloy may be added to the furnace but preferably is added to the molten metal stream between the furnace and the casting unit. Typical titanium additions range from 0.003 % to 0.015 %.

3.2. Casting Processes for Ingot

Direct chill (D.C.) *casting* is the primary method of ingot production in the aluminum industry [28]. Large ingots with either a rectangular or circular cross section are cast for fabrication by rolling to sheet or extruding to shaped profiles. Some circular cross section ingot is used as forging stock and starting material for rod and wire production. Figure 32 is a schematic illustrating the D.C. casting process developed around 1940, and Figure 33 shows a later modification in which level transfer is used to avoid turbulence with the associated oxide generation and hydrogen pickup. The level-pour method produces high-quality ingot for forged products of highest internal integrity. Direct chill ingot is usually cast in multiples, and the drop is terminated when the ingot length reaches the depth of the casting pit. A *continuous casting* process, in which the ingot is cast horizontally, as depicted in Figure 34, is widely used to produce a limited number of alloys when large amounts of ingot of one size are required.

Figure 32. Vertical direct chill (D.C.) casting

Figure 33. Level-pour mold assembly

Figure 34. Horizontal direct chill (D.C.) casting

A development in semicontinuous thick ingot casting is *electromagnetic casting* (EMC). In this method the traditional mold is replaced by an electromagnetic field that contains the column of molten metal until it enters the direct water cooling system. This produces a smooth-surface ingot free from the subsurface segregation of the older methods (Fig. 35) [29]. In some applications the EMC ingot can be fabricated without any prior surface machining or scalping. The major capital investment for scalping equipment and the melt loss, which occurs when scalper chips are remelted, are thus avoided.

Figure 35. Electromagnetic casting (EMC) process

Although thick-sectioned ingot is used for the bulk of aluminum alloy production, there is an increasing amount of continuous cast strip 6 to 18 mm thick. Productivity is lower, but casting at high solidification rates, closer to final shape, allows elimination of many energy-consuming steps, such as scalping, homogenizing, and hot rolling. All the major thin-section casting methods use the moving mold concept. Two of the most popular are the twin-roll Hunter Engineering process (Fig. 36) and the Hazelett twin-belt method (Fig. 37). Another method of casting close to the final shape is the Properzi process. A bar with a trapezoid cross section of about 32 cm^2 is continuously cast and rolled to a 9-mm diameter rod. This method provides stock for conductor wire production. High energy costs will accelerate the trend from thick ingot casting to the less energy-intense, thin-section, continuous casting.

Figure 36. Twin-roll Hunter caster

Figure 37. Hazelett twin-belt caster

3.3. Shaped Casting

Aluminum alloys are suitable for all common shaped casting methods: pressure die, permanent mold, sand casting, plaster, and investment [3, Chap. 2], [8, pp. 140 – 79]. The first three methods are the most commonly used. Pressure die casting (also called die casting) is the most widely used. Production by die casting, in terms of kilograms of metal cast, is more than twice that by permanent mold and sand casting combined. Typically, die castings are small in size, permanent mold castings are intermediate, and sand castings are largest. Section thickness usually increases in the same order. Die castings have the best surfaces, sand castings the worst.

Figure 38. Effect of sodium modification on microstructure of sand-cast A357.0 alloy as polished (120x)
A) Not modified; B) Modified

By far the most common casting alloys are the *hypoeutectic Al – Si* type (Si in the range 4 – 12 %). Die castings freeze more rapidly than permanent mold castings, which freeze more rapidly than sand castings. In order to maximize the mechanical properties in permanent mold and sand castings, modifiers are added to the hypoeutectic Al – Si alloys. The most common modifiers are Na and Sr, small additions (0.005 – 0.1 %) having the effect of refining the usually platelike silicon in the eutectic and giving it a rodlike form. These structural changes, illustrated in Figure 38 A and B, help to increase both strength and ductility of the alloys. Antimony (0.05 – 0.1 %) may also be used to refine the eutectic structure; however, it does not modify the alloy and the benefits are fully achieved only after heat treatment. The *hypereutectic Al – Si* alloys, used primarily in die casting, are modified with phosphorus, because aluminum phosphide is a potent nucleus for silicon.

3.3.1. Die Casting

In the pressure die casting process the molten metal is injected at high velocity into a reusable metal mold. The combination of the thin sections and high pressure insures a rapid freezing rate (Fig. 8), but the accompanying contamination by gas entrapped as the metal enters the mold detracts from the potential advantages of the fine metallurgical structure. In addition, gas contamination prevents heat treatment to develop precipitation strengthening. However, the true potential of die casting will be realized only by adopting techniques such as evacuating the mold before injecting the molten metal to minimize gas pickup.

Because the die is made of steel, with no give, the alloys used must be resistant to hot cracking and reasonably fluid to fill the thin sections typical of die castings. In general, the alloys contain at least 0.6 % Fe, to reduce "soldering," i.e., sticking of the cast part to the die as it is being ejected.

3.3.2. Permanent Mold Casting

Like die casting, permanent mold casting (also called gravity die casting) employs a reusable metal mold. Because the mold is gravity fed, the pouring rate is relatively slow, but the metal mold produces rapid freezing. Generally, permanent mold castings are larger, with thicker sections, than die castings. They have good mechanical properties and are usually sound, provided the alloys exhibit good fluidity and resistance to hot cracking. Mechanical properties can be improved further by heat treatment.

3.3.3. Sand Casting

Sand casting is the least expensive process, but the mold, which is formed by ramming sand mixed with bonding agent around a pattern, is not reusable. Like permanent mold casting, the sand mold is gravity fed. The principal disadvantages are slow cooling rates (Fig. 8), poor surface finish, and the minimum wall thickness of 4 mm. For the same alloy the slow cooling rate results in lower mechanical properties than with permanent mold casting. Nevertheless, sand casting is widely used, particularly if the casting is large or if the number of items to be produced does not justify the expense of a metal mold. An advantage of sand casting is that quite complex shapes can be made with alloys that are not particularly resistant to hot cracking because sand, unlike metal, can give when the alloy contracts on freezing.

3.4. Mill Products

Mill products or wrought products are produced by working ingot into the desired shape. The most common mill product is sheet, but significant quantities of plate, foil, extrusions, drawn tube, forgings, impacts, rolled rod, bar, shapes, and wire are produced [5, Chap. IX].

3.4.1. Plate, Sheet, and Foil

Plate, sheet, and foil are collectively referred to as *flat rolled products.* By convention, plate is thicker than 6.30 mm, sheet is between 0.15 mm and 6.30 mm, and foil is less than 0.15 mm thick. Flat rolled products are produced in rolling mills by passing the metal between two cylindrical rolls where it is subjected to high compressive forces to decrease thickness and increase length. When flat rolled products are made from ingot, initial passes are always at elevated temperatures, but final passes may be hot or cold, depending on desired thickness and temper. When continuously cast strip is the starting material, initial passes may be either hot or cold. Intermediate heating may be used to promote homogeneity and to remove prior strain. After the final rolling pass, heat-treatable alloys are annealed or solution heat treated and aged to produce the desired temper: some alloy-tempers require strain after quenching or aging. Nonheat-treatable alloys are annealed, partially annealed, or stabilized to produce the desired temper.

The size of ingot used for making flat rolled products varies widely in thickness, width, and length, depending on such factors as alloy, product size, and equipment size. Commercial ingot varies from 200 × 1000 mm to 600 × 1900 mm in cross section and is up to 9 m in length. The maximum size of flat rolled products depends on alloy, temper, and thickness. Maximum size of flat plate may vary from 1300 to 5300 mm wide and 23 – 25.4 m long. The maximum weight per piece commercially available is about 10 000 kg. Maximum size of flat sheet is 900 – 3350 mm wide and 4.6 – 19.8 m long. Sheet is also supplied in coils up to 2500 mm wide and 12 000 kg in weight. Foil is supplied in coils up to 1900 mm wide.

3.4.2. Extrusions

Extrusions are produced in extrusion presses by forcing an ingot or billet to flow from a container through a die to produce an elongated shape. The diversity of shapes and sizes is great, ranging from the simplest round rod to cross sections of great complexity. Table 7 summarizes the shape and size capabilities of the aluminum extrusion industry. Extrusions may be given thermal and mechanical treatments to produce the desired temper, or they may be given further mechanical deformation by drawing to tube or wire. Extruded stock can also be fabricated further by forging and drawing.

Table 7. Capabilities of the extrusion industry

Alloy	almost all commercial wrought alloys
Section thickness	1 – 300 mm
Diameter of circumscribing circle (smallest circle that completely encloses the shape)	6 – 300 mm
Weight/length	0.07 – 300 kg/m
Straight length	33.5 m max.
Weight per piece	1200 t max.
Tubing and pipe diameter	600 – 840 mm

The capability of extrusion presses is described in terms of the maximum force that the press can exert on the ingot or billet. Capacity ranges from a few hundred to 13000 t, but most presses fall in the range 1500 – 2500 t [3, Chap. 3].

3.4.3. Forgings

Forging is metalworking performed in hammers and presses. The compressive force is applied either locally – the different parts of the forging are progressively worked on open dies (hand forgings) – or over the entire surface of the forging in closed dies (die forgings). Forging is done both hot and cold. Starting stock is ingot or partly fabricated forms such as extruded bar, rolled bar, and plate. Forging hammers range in capacity from 0.2 to 25 t and make parts weighing up to 100 kg. Mechanical presses range in capacity from 300 to 10000 t and make parts weighing up to 25 kg with plan areas up to 0.3 m^2. Hydraulic presses range in capacity from 500 to 75000 t and make parts weighing from a few kg to 1500 kg with plan areas up to 3 m^2 [3, Chap. 5].

3.4.4. Other Mill Products

Tubing and pipe are produced as extrusions that may be reduced further, in both size and wall thickness, by subsequent drawing through dies. An alternate method is forming sheet into a long hollow shape or a spiral and butt welding the edges to make a tube or pipe.

Rolled rod, bar, and some shapes are produced in rolling mills. For this purpose the rolls have a series of circumferential grooves to impart the desired shape.

Wire may be round, square, hexagonal, or octagonal in cross section. By convention it is less than 10 mm in diameter or between flats. It is produced by drawing rod or bar through a series of dies. Cable is made by stranding wire. ACSR (aluminum conductor, steel reinforced) is made by stranding aluminum wires around steel wire.

Impacts are parts made in a confining die from a metal slug by a rapid, single-stroke application of force through a punch. The metal flows back along the punch or through an opening in the punch or die.

3.5. Powder and Paste

Most aluminum powder is made by atomizing molten aluminum with compressed air; the particle size is controlled by the atomizing conditions. The particles are very rough but approximately equiaxial. Atomized powders are used in a number of chemical and metallurgical procedures.

Pigments are usually produced by ball milling atomized powder in the presence of lubricants to produce thin flakelike shapes having length and breadth 10 to 100 times greater than thickness. After milling, the pigment may be dried at moderately elevated temperature at reduced pressure, or solvent may be added to make a paste.

4. Commercial Alloys, Products, and Uses

A number of systems are used throughout the world to designate aluminum alloys and tempers. In the discussion that follows, the Aluminum Association designations are used for casting and wrought alloys.

4.1. Aluminum Association Designations for Alloys and Tempers

The Aluminum Association designation system for *casting alloys* is shown in Table 8 [6, pp. 8 – 9]. In the 1xx.x group the second and third digits indicate the minimum aluminum percentage above 99.00 %. In the 2xx.x through 9xx.x groups, the second and third digits have no compositional significance but serve only to identify different alloys within the group. The digit to

the right of the decimal point indicates product form: 0 for castings; 1 and 2 for ingot, 2 indicating a narrower composition range within the broader limits of the xxx.1 composition. A modification of the original alloy or impurity limits is indicated by a letter prefix. (I, O, Q, and X may not be used as the prefix.)

Table 8. Casting alloy designation system

Major alloying element	Designation
≧ 99.00 % Al or purer	1xx.x
Cu	2xx.x
Si + Cu and/or Mg	3xx.x
Si	4xx.x
Mg	5xx.x
Zn	7xx.x
Sn	8xx.x

The Aluminum Association system for *wrought alloys* is shown in Table 9 [6, pp. 7 – 8]. In the 1xxx group the last two digits indicate the minimum aluminum percentage above 99.00 %. For example, the alloy 1060 is ≧ 99.60 % Al. Only one alloy, 1100, has a specified alloying addition, 0.05 – 0.20 % Cu. In the 2xxx through 7xxx groups the last two digits have no composition significance but serve only to identify individual alloys in the series. The second digit indicates a modification of the original alloy. The prefix X indicates an experimental wrought alloy.

Table 9. Wrought alloy designation system

Major alloying element	Designation
≧99.00 % Al	1xxx
Cu	2xxx
Mn	3xxx
Si	4xxx
Mg	5xxx
Mg + Si	6xxx
Zn	7xxx
Other	8xxx

Temper designations are based on the sequence of basic treatments used to produce the temper (Table 10) [6, pp. 9 – 12]. Some basic treatments are applicable to both wrought and casting alloys. Variations of basic tempers for *non-heat-treatable* alloys are listed in Table 11. The third digit, when used, indicates a variation of a two-digit temper. It is used when the temper or mechanical properties, or both, differ from but are close to those for the two-digit H temper designation, or when some other product characteristic is affected significantly. Variations of the basic tempers are shown for *heat-treatable* alloys in Table 12. Additional digits, the first not zero, may be added to designation T1 through T10 to indicate a variation in treatment that significantly alters the characteristics of the product.

Table 10. Basic temper designations

Designation	Description
F	*as fabricated.* Applies to the products of shaping processes in which thermal conditions or strain hardening is not specially controlled. For wrought products there are no mechanical property limits.
O	*annealed.* Applies to wrought products annealed to the lowest strength temper, and to cast products annealed to improve ductility and dimensional stability. The O may be followed by a digit other than zero.
H	*strain hardened (wrought products only).* Applies to products strengthened by strain hardening, with or without supplementary thermal treatment to reduce strength. The H is always followed by two or more digits.
W	*solution heat treated.* An unstable temper, applies only to alloys aging spontaneously at room temperature after solution heat treatment. The designation is specific only when the period of natural aging is indicated, e.g., W 1/2 hr.
T	*thermally treated, stable tempers other than F, O, or H.* Applies to products thermally treated, with or without supplementary strain hardening, to produce stable tempers. The T is always followed by one or more digits.

Table 11. Non-heat-treatable alloy-tempers

Designation	Description
H 1	*strain hardened only.* Applies to products strain hardened to the desired strength without supplementary thermal treatment. The number following this designation indicates the degree of strain hardening.
H 2	*strain hardened and partially annealed.* Applies to products strain hardened more than the desired final amount and then reduced in strength to the desired level by partial annealing. The number following this designation indicates the degree of strain hardening remaining after partial annealing.
H 3	*strain hardened and stabilized.* Applies to products strain hardened and stabilized by low-temperature thermal treatment or heating during fabrication. This designation is applicable only to those alloys which, unless stabilized, gradually age soften at room temperature. The number following this designation indicates the degree of strain hardening remaining after stabilization.

Table 12. Heat-treatable alloy-tempers

Designation	Description
T 1 ∗	cooled from an elevated-temperature shaping process and naturally aged to a substantially stable condition.
T 2 ∗	cooled from an elevated-temperature shaping process, cold worked, and naturally aged to a substantially stable condition.
T 3	solution heat treated, cold worked, and naturally aged to a substantially stable condition.
T 4	solution heat treated and naturally aged to a substantially stable condition.
T 5 ∗	cooled from an elevated-temperature shaping process and artificially aged.
T 6	solution heat treated and artificially aged.
T 7	solution heat treated and overaged/stabilized. Applies to wrought products artificially aged after solution heat treatment and carried beyond maximum strength to control characteristics other than mechanical properties.
T 8	solution heat treated, cold worked, and artificially aged.
T 9	solution heat treated, artificially aged, and cold worked.
T 10 ∗	cooled from an elevated-temperature shaping process, cold worked, and artificially aged.

∗ Press quenched temper designations.

4.2. Alloys for Castings

Over 230 compositions for casting alloys have been registered with The Aluminum Association [13]. Nominal compositions of the most common alloys are shown in Table 13. Also shown are a few alloys, e.g., 201.0, 390.0, and 852.0, which are used in small volume but illustrate the range of commercial compositions. Some properties that are affected by compositions but not by temper are given in Table 13.

Casting alloys are ranked by suitability for casting, i.e., by their foundry characteristics, in Tables 14 and 15. The rankings are relative to other alloys in each casting category; i.e., die, permanent mold, or sand. Resistance to hot cracking is the ability to withstand contraction stresses on cooling. Die filling capability and fluidity indicate the ability of the molten metal to flow into all parts of the mold. Die castings are ranked on their tendency to solder to the die. Pressure tightness is an indication of the soundness of the cast part and the freedom from leakage of fluid under pressure. Solidification shrinkage reflects the alloy not being subject to shrinkage porosity.

Typical tensile properties of some die casting alloys are shown in Table 14 [30, ASTM B85].

Table 13. Composition and properties of casting alloys

Alloy	Product[a]	Nominal composition, wt %					Properties[b]			
		Cu	Mg	Mn	Si	Others	*m.r.*, °C	$\varrho^{25\,c}$, g/cm^3	$\bar{\alpha}$, 10^{-6}/K	*E*, GPa
201.0	S	4.6	0.35	0.35		0.70 Ag, 0.25 Ti	535 – 650	2.77	19.3	71.0

Table 16 lists tensile properties of some permanent mold and sand castings, minimum guaranteed values for separately cast test bars [30, ASTM B26, ASTM B108].

Castings are also ranked by product characteristics (Tables 14 and 15). Resistance to corrosion is based on general corrosion in a standard salt spray test. Machining is a composite rank based on ease of cutting, chip characteristics, quality of finish, and tool life. Polishing is based on ease of polishing and quality of finish. Electroplating rank indicates the ability to take and hold an electroplated coating. Anodizing rank is based on lightness of color, brightness, and uniformity of the clear anodized coating applied in sulfuric acid electrolyte. The chemical oxide coating is ranked on the combined resistance of coating and base alloy to corrosion. The elevated temperature strength is based on tensile and yield strength up to 260 °C. Die castings are not generally solution heat treated, but some permanent mold and sand castings are. Castings may be given a low-temperature aging or stabilization treatment without a separate solution heat treatment.

Some uses of aluminum alloy castings are listed in Table 17 (see next page).

4.3. Alloys for Wrought Products

Almost 400 domestic and international chemical compositions have been registered with the Aluminum Association for wrought alloys [14], and more than 1000 alloy-temper-product combinations have been described [6], [8].

Nominal compositions are listed in Table 18. Typical properties that depend on composition but not on temper are illustrated in Table 19. The melting range is for a thoroughly homogenized structure. The modulus of elasticity is an average of tension and compression. The modulus is about 2 % higher in compression than in tension.

Some characteristics and properties for selected alloy-tempers are given in Table 20. Corrosion ratings A through E are relative ratings, in order of decreasing merit, based on exposures to sodium chloride solution by intermittent spraying or immersion. Alloys with A and B ratings can be used in industrial and seacoast atmospheres without protection. Alloys with C, D, or E ratings generally should be protected, at least on faying surfaces. The general corrosion ratings of thick sections of 2011-T3, 2024-T3, and 7075-T6 would be lower than given in

Table 17. Typical uses of aluminum casting alloys

Alloy	Typical applications
201.0	applications requiring highest strength and moderate elongations (T6): structural castings, aerospace parts, truck and trailer castings. Applications requiring elevated-temperature strength (T6, T7): gasoline engine cylinder heads and pistons, rocker arms, connecting rods; turbine and supercharger impellers; missile fins. Applications requiring high strength and energy absorption capacity: gear housings, aircraft landing gear, ordnance
355.0	applications requiring good castability, high strength, and pressure tightness: pump bodies, liquid-cooled cylinder heads, crankcases, aircraft fittings, impellers
C355.0	stronger and more ductile than 355.0: aircraft, missile, and other structural parts
356.0	intricate castings requiring good strength and ductility: transmission cases, truck axle housings, truck wheels, cylinder blocks, cylinder heads, fan blades, marine hardware
A356.0	stronger and more ductile than 356.0: aircraft and missile parts, auto transmission cases
A357.0	aircraft and missile parts requiring weldability, strength, and toughness
360.0	applications requiring corrosion resistance better than 380.0
380.0	most widely used die-casting alloy: lawnmower housings, gear cases, cylinder heads for air-cooled engines, parts for auto and electrical industries
390.0	auto cylinder blocks, four-cycle air-cooled engines, air compressors, parts requiring abrasion resistance, low thermal expansion, or elevated-temperature strength
413.0	thin-walled intricate designs requiring excellent castability
B 443.0	general-purpose alloy: cooking utensils, waffle irons, architectural and marine fittings
513.0	castings requiring anodic finishes and corrosion resistance: marine fittings, auto trim, pipe couplings
518.0	escalator parts, conveyor components, aircraft and marine hardware
520.0	strong and ductile structural uses: aircraft fittings, trucks and bus frame components, brackets
713.0	general-purpose alloy: large castings requiring strength without heat treatment
852.0	bearings and bushings for heavy loads

Table 20. The corrosion ratings of 5182 and 5456 may be lowered by exposure to elevated temperature for long periods.

Stress-corrosion cracking ratings are based on service experience and laboratory tests of specimens exposed to the 3.5 % sodium chloride alternate immersion test.

A) No known instance of failure in service or laboratory tests
B) No known instance of failure in service, limited failures in laboratory tests on short transverse specimens
C) Service failures with sustained tension stress acting in short transverse direction relative to grain structure, limited failures in laboratory tests of long transverse specimens
D) Limited service failures with sustained longitudinal or long transverse stress

Ratings A through D for workability and A through E for machinability are relative ratings in order of decreasing merit. Ratings A through D for weldability, brazeability, and solderability also are relative ratings. For example:

A) Generally weldable by all commercial procedures and methods
B) Weldable with special techniques or for specific applications that justify preliminary trials or testing to develop welding procedure and weld performance
C) Limited weldability because of crack sensitivity or loss in resistance to corrosion and mechanical properties
D) No commonly used welding methods have been developed

A wide variety of alloy-temper-product combinations are available as indicated by the partial listing in Table 21. Some typical uses for wrought aluminum alloy products are in Table 18.

Table 18. Nominal compositions and uses of wrought aluminum alloys

Alloy	Percentage of alloying elements (balance is Al + normal impurities)								Uses
	Si	Cu	Mn	Mg	Cr	Ni	Zn	Others	
1060			≧ 99.60 % Al						chemical equipment, railroad tank cars
1100		0.12	≧ 99.00 % Al						sheet metal work, spun holloware, fin stock
1199			≧ 99.99 % Al						electrolytic capacitor foil, chemical equipment, railroad tank cars

∗ The Australian and Canadian designations refer to the Aluminum Association .2 alloys, whereas the German, Japanese, and British refer to the .0 alloys. The Italian designations generally refer to both .0 and .2 alloys. For example, AP 309 is equivalent to 355.2 and L78 is equivalent to 355.0;
∗∗ AS for .1 alloys, e.g., AS 601 for 356.1

4.4. Comparison of Designation Systems

The Aluminum Association's wrought alloy designation system is in common use worldwide. International wrought alloy registrations are made through The Aluminum Association's International Accord. Table 22 (see above) compares the designations of approximately equivalent casting alloys, and Table 23 (see next page) does the same for wrought alloys. Much more extensive lists are given in [31]. Inspection of Table 23 shows that the designations of wrought alloys are similar, or the same, in the United States, Australia, Canada, Italy, and Japan. The systems in Germany, Austria, the Netherlands, and Switzerland are similar. National organizations issuing specifications and designations are listed in Table 24 for selected countries [31, Appendix F].

Table 24. Organizations that issue specifications

Country	Organization, city
Australia	Standards Association of Australia, North Sydney
Austria	Österreichisches Normungsinstitut, Wien
Canada	Canadian Standards Association, Etobicoke, Ontario
China, People's Republic of	China Association for Standardization, Peking
France	Association Française de Normalisation, Paris
Germany	Deutsches Institut für Normung, Berlin
International	International Organization for Standardization, Genève
Italy	Ente Nazionale Italiano di Unificazione, Milano
Japan	Japanese Industrial Standards Committee, Tokyo
Netherlands	Nederlands Normalisatie-instituut, Rijswijk
Spain	Instituto Nacional de Racionalizacion del Trabajo, Madrid
Switzerland	Verein Schweizerischer Maschinen Industrieller, Zürich
Russia	Russian Committee for Standards, Moskva
United Kingdom	British Standards Institution, London
United States	The Aluminum Association, Washington

4.5. Alloys for Powder Metallurgy Products

Powder metallurgy is used to achieve unique combinations of properties not obtainable by other techniques. Two categories of powder-metallurgy products are made: high-performance wrought products, and sintered parts.

Sintered parts are made from mixtures of unalloyed powders or mixtures of unalloyed and alloyed powders. Lubricant to prevent aluminum adhering to compacting tools may be mixed with the powder or applied to the tools. The powders are usually compacted cold into the desired shape in automatic powder metallurgy presses. The part then is sintered in an inert atmosphere at a temperature that causes limited melting to promote interparticle bonding as well as alloying of the components. The part may be used as sintered and naturally aged (T1), or it may be heat treated and aged to increase strength (T6). Sintered parts retain some porosity, which is controlled by the compacting and sintering conditions. Table 25 summarizes composition and properties of powder-metallurgy alloys [34].

Table 25. Composition and properties of aluminum powder-metallurgy alloys

Alloy	Nominal composition, wt %						Temper	Density, g/cm^3	Tensile strength, MPa	Yield strength, MPa	Elongation, % in 25 mm	Comments

5. Manufacture of Articles from Aluminum Products

Aluminum alloy mill products and castings are the starting materials for the manufacture of a great many articles, ranging from agricultural equipment to zippers. The value added by subsequent operations varies with the article, ranging from a small fraction to many times the cost of the mill product or casting. The major manufacturing operations are shaping, joining, and finishing.

5.1. Shaping

The shapes of aluminum products are changed by deformation and metal removal. *Deformation* involves stretching, bending, upsetting, and extruding and changes the metallurgical structure. Little or no metal is lost. On the other hand, *metal removal* usually is accompanied by substantial loss of metal, but there is no change in

change in metallurgical structure. Removal includes cutting, grinding, and chemical dissolution [3, Chaps. 6 – 8],[8, pp. 180 – 90].

The choice of method is determined by many factors, including alloy-temper, the form of the mill product, and the form and characteristics of the final product. Table 20 classifies a number of alloy-tempers according to workability; information on additional alloy-tempers is in [3, Chaps. 6 – 8], [8, pp. 46 – 9]. The machinability ratings in Tables 14 and 20 are based on the nature of the machine chips (small, or long and stringy), surface finish, and tool wear. These ratings can serve only as a preliminary guide because the type and shape of machining tools, cutting speeds, lubrication, and other factors also must be considered [3, Chap. 8], [8, pp. 187 – 90].

5.2. Joining

Aluminum products are joined by many commercial methods: mechanical, metallurgical, and adhesive [3, Chaps. 11 – 15], [12], [8, pp. 191 – 203].

5.2.1. Mechanical Joining

Mechanical joining is used to join aluminum articles to other aluminum articles and to other materials. Aluminum alloy threaded fasteners, rivets, bolts, and nails are often used. Also used often are lock seams, crimping, and other integral joints that do not use separate fasteners. Generally, the condition of the aluminum surface does not have an effect on the initial strength of the joint, but surface preparation and post-joining protection have major effects on leak tightness and durability.

The most ubiquitous examples of mechanical joints are probably in two-piece beverage cans. Cross sections through two parts of an end are shown in Figure 39. The end is joined to the can body with a double-lock seam (Fig. 39 A). The tab is joined to the end by an integral rivet (Fig. 39 B). The rivet is first formed as a small bubble in the can end, and the tab is placed on the end so that the bubble goes through a hole in the tab. Finally, the bubble is flattened to fasten the tab to the end.

Figure 39. Mechanical joints in beverage can (≈ 2.5X)
A) Double seam joining end to body; B) Integral rivet joining tab to end

5.2.2. Metallurgical Joining

The metallurgical joining processes are welding [12, pp. 373 – 99, 534 – 44, 609 – 768], brazing [12, pp. 1022 – 32], and soldering [3, pp. 525 – 48]. These methods all involve establishing metal-to-metal bonds by melting. Welding is achieved also by solid-state processes involving deformation to break up oxide films and insure contact between faying surfaces.

Aluminum alloys vary widely in their suitability for joining by metallurgical techniques. Some alloy-tempers are categorized in Tables 15 and 20; information on other alloy-tempers is in [8, pp. 46 – 49, 144]. The rankings are based on how easily defect-free joints are made and how closely the joints approach the properties, corrosion resistance, and finishing characteristics of the parent metal. Aluminum alloy specialty products made for joining applications include filler wire for welding (Table 26) and brazing (Table 27) and brazing sheet (Table 28). Surface pretreatment and protection of the surface during metallurgical joining are important factors affecting the quality of the finished joint.

Table 26. Filler alloys for inert gas welding of aluminum alloys

5.2.3. Adhesive Bonding

Adhesive bonding is widely used to join aluminum to itself and to other materials. Applications range from aircraft structures to packaging. Suitability for adhesive bonding is not usually a factor in alloy selection; the alloy is selected on its other characteristics and properties. Surface preparation of the adherends strongly affects initial strength and durability. Several pretreatment methods are in use. Adhesive bonding is sometimes combined with other joining methods such as spot welding (weldbonding) and mechanical joining [35].

5.3. Cleaning and Finishing

An outstanding characteristic of aluminum alloys is the ability to accept decorative and protective finishes. Extensive research and development has resulted in many different types of finishes and many processes to produce finishes [3, Chaps. 16 – 22], [11, pp. 571 – 610]. Because cleaning and pretreating the surface prior to applying the final coating are so important, the manufacture of a commercial article usually involves a sequence of cleaning and finishing steps. Generally, the procedures do one or more of the following:

1) Remove dirt, lubricant, oxide, and other debris left by prior operations
2) Remove some of the base metal
3) Deform the surface of the base metal
4) Convert aluminum to aluminum oxide
5) Coat with other materials

Figure 40. Operations sequence in sulfuric acid anodizing of architectural parts

Solution no.	Type of solution	Composition	Operating temperature, °C	Cycle time, min
1	alkaline cleaning	alkali, inhibited	60 – 70	2 – 4
2	alkaline etching	NaOH, 5 wt %	50 – 71	2 – 20
3	desmutting	HNO_3, 25 – 35 vol %	room	2
4	anodizing	H_2SO_4, 15 wt %	21 – 25	5 – 60
5	sealing	water, pH 5.5 – 6.5	100	5 – 20

Figure 41. Preplating surface preparation sequence suitable for alloys 1100, 3003, 3004, 2011, 2017, 2024, 5052, 6061, 208, 295, 319, and 355

Solution	Type of solution	Composition	Concentration	Operating temperature, °C	Cycle time, s
1	acid dip	H_2SO_4	15 vol %	≥ 85	120 – 300
2	acid dip	HNO_3	50 vol %	room	15
3	zincating	NaOH	525 g/L	16 – 27	30 – 60
		ZnO	100 g/L		

The multistep nature of finishing processes is illustrated in Figure 40 by showing a sequence for anodizing architectural parts [11, p. 590]. One sequence for preparing alloys for electroplating is shown in Figure 41 [11, p. 604]. Although many methods are used, they can be divided into nine categories:

1) mechanical
2) chemical cleaning
3) etching
4) brightening
5) chemical conversion coating
6) anodizing
7) metal coatings (immersion and electroless coating, electroplating)
8) painting and organic coatings
9) enameling

5.3.1. Mechanical Cleaning and Finishing

Mechanical methods may be used to remove asperities, smoothing the surface, or to produce a uniformly rough surface. The method can remove metal (e.g., grinding, polishing, buffing, blasting) or deform the surface (e.g., embossing, hammering, shot peening). Surface appearance

ranges from mirrorlike to hammered, depending on the method and alloy.

5.3.2. Chemical Cleaning and Finishing

Chemical cleaning and finishing treatments are used to:

1) Remove oxides, lubricants, and other matter left on the surfaces from prior operations or storage
2) Smooth or roughen surfaces to impart specular or mat appearances
3) Develop decorative or protective coatings
4) Deposit metallic films

The surfaces that result from these treatments are usually a pretreatment for other finishes, but they are sometimes the final surface of the article.

The least aggressive cleaners are the *organic solvents.* They are used to remove oils and greases but do not remove oxides or metal. *Alkaline cleaners* range from mild to aggressive. They are commonly used to dissolve or remove dirt and can be formulated to etch. Etching is controlled by inhibitors, such as silicates. *Acid cleaners* are used to remove oxide films, welding and brazing fluxes, and smut from other cleaning operations. Smut is a term applied to the dark deposit formed when alloys containing high concentrations of silicon, copper, iron, and manganese are etched in alkaline solutions.

5.3.3. Chemical Etching

Chemical etching removes metal to produce mat finishes and to reduce or remove surface scratches, extrusion die lines, and other small defects. Etching promotes surface uniformity, thus simplifying subsequent finishing treatments. *Alkaline etching* works well with most aluminum alloys, provided etching is followed by desmutting. However, *acid etching* is preferred for 99.99+ aluminum and alloys containing large amounts of magnesium or silicon.

The most common alkaline etching solution is NaOH plus a sequestering agent to retard the formation of hydrated alumina. Acid etching solutions are usually nitric – hydrofluoric and sulfuric – chromic acids. The high-silicon alloys are also etched in hydrofluoric acid solutions.

5.3.4. Chemical and Electrolytic Brightening

Chemical brightening, chemical polishing, and bright dipping are synonymous. The rough surface is smoothed and brightened by dissolving the high spots. Acid oxidizing solutions are used most commonly, for example, phosphoric – nitric and phosphoric – sulfuric acids. The solutions can be tailored to specific alloys.

Electrolytic brightening, or electropolishing, also is used to produce smooth bright surfaces. The aluminum is the anode. A variety of baths are used, including fluoroboric acid, sodium carbonate – trisodium phosphate, and sulfuric – phosphoric – chromic acid. These brightening processes are followed by desmutting, anodizing, and sealing.

The surfaces produced range from specular to diffuse. Generally the quality of finish is highest for super pure aluminum (99.99 %) containing up to 2 % Mg and high-purity aluminum (99.7 to 99.85 %). However, these finishing methods are also applied to other alloys: e.g., 5457, 5357, 6463, 6063, 5052, 1100, 5005, 3003, and 6061, the quality of finish decreasing generally in this order.

5.3.5. Chemical Conversion Coating

Chemical conversion coatings are surface films formed by reactions that convert the surface of the aluminum into one of the components of the coating. Because the coatings are integral with the surface, they have excellent adherence. Although conversion coatings are thinner and less protective than anodic coatings, they give adequate corrosion and abrasion protection for many applications and are excellent substrates for lacquers, paints, plastic films, adhesives, and lubricants.

Many solutions have been used, but they generally contain agents to do at least two things: (1) dissolve the original aluminum oxide coating and some of the underlying aluminum and (2) form insoluble aluminum compounds (oxides, phosphates, or chromates) on the surface. Inhibitors are sometimes added to control the rate at which aluminum dissolves.

5.3.6. Anodizing

Anodizing converts the aluminum surface to aluminum oxide. The alloy and the conditions for forming the oxide can be chosen to produce a wide variety of useful characteristics. Uses include:

1) Decorative colors and textures
2) Substrates for paints, metal plating, adhesives, and photographic and lithographic emulsions
3) Corrosion resistance
4) Wear resistance
5) Electrical insulation
6) Quality control (inspection of parts for cracks and metallurgical nonuniformity)

Two principal types of anodized coatings are recognized: barrier and porous (Fig. 42) [36], [37]. The mechanism for the formation of the barrier coating is ionic: aluminum ions from the base metal combine with the oxygen of water in the electrolyte. The limiting thickness of the barrier layer is determined by the distance that the ions can penetrate at the applied potential, about 140 nm/V. If the oxide is appreciably soluble in the electrolyte, current continues to flow, and a relatively thick, porous oxide layer can develop.

Figure 42. Structure of anodic coatings
A) Two principal types; B) Structure of 120-V phosphoric acid coating with dimensions of pore, cell, cell wall, and radius of curvature shown in nm

The limiting barrier layer thickness is then less than 140 nm/V. The porous oxide cells are predominately hexagonal, and each cell contains a pore. The dimensions of the cells and pores depend primarily on the potential, and secondarily on the electrolyte. The porous anodic coatings are essentially amorphous and can be sealed in boiling water. Anodizing at voltages above 100 V can form some eta alumina (η-Al_2O_3).

Some conventional anodizing processes are shown in Table 29 (next page). The most common electrolytes for conventional thick porous anodized coatings are *sulfuric acid* solutions. These coatings have a wide range of characteristics; the conventional coatings are decorative or protective and range in thickness from 4 to 30 µm. *Chromic acid* anodized coatings are thinner and less abrasion resistant than the sulfuric acid coatings, but they are more flexible and more resistant to deformation and heating without crazing. *Oxalic acid* anodized coatings are somewhat harder than the sulfuric acid coatings.

Table 30 (page after next) lists a number of processes that produce thicker and harder anodized coatings than the conventional processes.

Alloy Composition. The anodizing characteristics of aluminum are affected significantly by impurities and alloying elements. Alloys containing copper and silicon require higher voltage than unalloyed aluminum to produce a given thickness, but magnesium lowers the voltage. Appearance, continuity, abrasion resistance, dielectric strength, composition, and structure of the anodic layer are all affected by alloy composition.

Coloring. Pure aluminum (99.95 %) produces the most transparent coating, dullness generally increasing with the impurities and alloy content. Anodic coatings are colored by certain alloying elements (integral colors). Aluminum – silicon alloys such as 4043 provide durable gray coatings widely used as exterior architectural finishes. Chromium and copper in solid solution yield light gold finishes, and manganese imparts tan to brown shades.

Porous anodic coatings can be impregnated with organic and inorganic dyes and pigments during anodizing by incorporating the dyes and pigments in the electrolyte or during a post-anodizing treatment.

Table 29. Conventional anodizing processes, [11, p. 587]

Process bath	Amount, wt %	Temperature, °C	Duration, min	Voltage, V	Current density, A/dm^2	Film thickness, µm	Appearance	Remarks

Water	99.25							

* The voltage is a rising ramp from 50 to 500 V; the amperage is determined by the voltage

Sealing. Many anodic coatings are porous and subsequently are sealed to improve resistance to staining, resistance to corrosion, and durability of the colors. Sealing is accomplished by immersion in hot water. The mechanism is generally thought to involve conversion of the essentially amorphous alumina surface of the anodic coating to crystalline alpha alumina hydrate, increasing the volume and therefore closing the pores.

5.3.7. Metal Coatings

Certain metals can be deposited on the surface of aluminum articles by reaction (immersion and electroless processes) or electrolysis (electroplating). The former are usually functional, but the latter can be functional or decorative.

Immersion coating involves the reduction of cations by aluminum, whereas *electroless coating* involves the reduction of cations by reducing agents in the solution. Immersion coatings of zinc and tin plus copper are used primarily as a base for electroplating other metals. Tin has been used on aluminum aircraft engine pistons. Nickel is the most common electroless coating on aluminum, but cobalt, copper, gold, palladium, etc., can also be deposited by this method.

Metals are *electroplated* on aluminum for appearance; increased wear-, abrasion-, or erosion-resistance; lower electrical resistance; better solderability; and improved friction characteristics. Table 31 shows a few uses of electroplated products.

Electroplating of aluminum articles is made more complicated by the nature of the aluminum oxide surface and the reactivity of aluminum when the oxide is removed. Additional complications result from reactions between aluminum and the electroplating solutions, and galvanic reactions between aluminum and the plated metal. The metallurgical structure of aluminum alloys consists of solid solutions, constituents, dispersoids, and precipitates, each having a different reactivity. All of these forms must be considered to obtain useful electroplates.

5.3.8. Paints and Organic Films

Aluminum surfaces that have been properly pretreated are excellent substrates for paints and

Table 31. Uses of electroplated aluminum products, [11, p. 602]

Product	Form	Preplating treatment	Electroplating system	Thickness, µm	Purpose

organic films. Optimum *pretreatment* is multistep and may include combinations of mechanical cleaning, chemical cleaning, conversion coating, anodizing, and priming. Pretreatment ranges in effectiveness from solvent cleaning, marginal even for interior service, to anodizing, which can give corrosion protection in severe environments. Conversion coatings are excellent bases for organic coatings and laminating adhesives, and they provide some corrosion protection.

Primer coatings are formulated specifically to promote the adherence and performance of finish coats. *Plastic coatings,* e.g., vinyl, epoxy, butyrate, polyethylene, and nylon, can be applied in thicknesses of 0.1 – 0.5 mm by melting fine particles of resin on the surface to form a continuous film. *Plastic films,* e.g., poly(vinyl chloride) and poly(vinyl fluoride), are bonded adhesively to aluminum.

5.3.9. Porcelain Enamels

Porcelain enamel is a glass film fused onto the surface of the metal. The components of the enamel, a mixture of glass and inorganic pigment particles, or frit, are applied as a water suspension. The part and the mixture are heated to dry and fuse the frit. The frit must melt below 550 °C, and its coefficient of thermal expansion must be close to that of the aluminum substrate.

Compositions of frits are complex, as illustrated by three examples in Table 32 [11, p. 511]. The lead-based enamels have high gloss and good weather resistance. The phosphate base has a lower melting temperature but is not as resistant to water. The barium enamels melt at higher temperature and have good resistance to chemicals.

Aluminum alloys for porcelain enameling are limited by their melting range, chemical compatibility with the glass, and strength after firing. The commonly used alloys are 1100, 3003, 6061, 443.0, and 356.0. Surface preparation consists of (1) removing dirt, grease, and oil; (2) removing thickened, irregular oxide films; and (3) applying a conditioning film.

Table 32. Compositions of frits

Constituent	Composition, wt%		
	Lead enamel	Barium enamel	Phosphate enamel
PbO	14 – 45	–	–

F	–	–	5
TiO_2	15 – 20	*	*

* 7 to 9 wt % added to frit during mill preparation of the enamel slip

6. Corrosion Resistance of Aluminum

Corrosion literature deals with the theory and the many observations of the role of metallurgical structure, environment, stress, and time [4, Chap. 7], [8, pp. 204 – 36]. Most of the effort has been pragmatic, and the information consists of systematic observations on the performance of a variety of alloys, tempers, and protective systems in natural and artificial environments.

The oxide that forms on aluminum is bonded strongly to the metal and reforms very rapidly after damage in most environments. Consequently the corrosion resistance of aluminum is typically excellent, even though pure aluminum is more electropositive than all other structural metals except magnesium and probably beryllium. The stability region of the oxide is shown in a Pourbaix diagram of pH vs. potential (Fig. 43) [38]. Aluminum is protected by its oxide film, i.e., it is passive, in the pH range 4 – 8.5. The exact range depends on the form of oxide, the rate at which the oxide dissolves in the electrolyte, and the temperature. Outside the passive range, in both acid and alkaline solutions, aluminum can corrode. However, in some cases, corrosion does not occur even outside the passive range if the oxide is not soluble in the electrolyte or if the oxide is maintained by a strongly oxidizing solution.

Figure 43. Pourbaix diagram for aluminum with an oxide film of hydrargillite ($Al_2O_3 \cdot 3H_2O$) at 25 °C

6.1. Pitting Corrosion

Corrosion of aluminum in the passive region is usually by pitting in the presence of halides and oxygen. In this kind of environment, aluminum is easily polarized to its pitting potential; i.e., it develops an electrode potential that exceeds the pitting potential. In deaerated solutions this is not possible. In general, the pitting potentials of aluminum in solutions of most other salts are significantly more cathodic than they are in halides, and the pitting potential is not reached.

6.2. Electrode Potentials

Because many types of corrosion proceed by electrochemical mechanisms, the electrode potentials (or solution potentials) of the phases in aluminum alloys are important for understanding corrosion. Electrode potentials are the potentials of the phases versus a reference electrode in a standard solution. Work by Brown and Mears led to wide acceptance of the 0.1 N calomel electrode, an aqueous solution containing 53 g NaCl + 3 g H_2O_2 per liter, and 25 °C for the study of aluminum alloys [1, p. 209]. The potentials for this solution are particularly useful because the behavior is similar to the behavior observed in marine and other saline environments. The potential values given here are referred to the 0.1 N calomel electrode, although the saturated calomel electrode is now preferred as the reference electrode. The saturated calomel electrode gives potentials that are 0.08 V more cathodic.

Figure 44 shows the effects of the major alloying elements on the solution potential of solid-solution alloys. Table 33 gives the solution potentials of some casting alloys, Table 34 some wrought alloys, and Table 35 some second-phase constituents in aluminum alloys.

Table 33. Electrode potentials of casting alloys

Alloy	Temper	Type *	Potential, V **	Nominal composition, wt%

∗ Versus 0.1 N calomel electrode

The type and amount of corrosion are related to the electrode potentials of the phases in aluminum alloys. The second phases usually have potentials that are significantly different from the aluminum matrix. The matrix can be either pure aluminum or solid solutions of other elements and aluminum. When the second phase particles are anodic to the matrix, the particles can be dissolved from the surface of the metal. When the second phase is cathodic, second phase particles can accelerate corrosion of the matrix adjacent to the particles. Adjacent areas can also have different amounts of an element in solid solution, thus creating a significant anodic – cathodic relationship. This is common in some tempers of heat-treatable alloys. These metallurgical structure factors are often involved in localized, intergranular, and exfoliation corrosion and in stress-corrosion cracking.

Differences in electrode potentials between two aluminum alloys or between an aluminum alloy and another metal can also lead to galvanic corrosion. Table 36 gives electrode potentials for some other metals. A related situation occurs when a cathodic metal precipitates on the aluminum surface during corrosion; the cathodic metal (e.g., Cu, Hg, Pb) may enter the system from the environment or the alloy. This is sometimes called deposition corrosion.

Table 36. Solution potentials of some nonaluminum base metals

Nickel	−0.07
Chromium	−0.40 to +0.18

∗ Versus 0.1 N calomel electrode

However, potential differences can be used to advantage. Alclad products consist of a strong core alloy clad with alloy anodic to the core, usually by 0.08 – 0. 10 V Corrosion will penetrate the cladding but not enter the core; instead, corrosion proceeds laterally as the cladding is consumed. Table 37 lists alloy pairs used in Alclad products.

Table 37. Combinations of alloys in Alclad products

Core alloy ∗	Cladding alloy

	7011		0.20	1.3	4.8	0.12
7178	7072				1.0	

∗ Nominal compositions shown in Table 18

6.3. Crevice Corrosion

A concentration cell may be set up if there is an electrolyte between two aluminum faying surfaces, or between an aluminum surface and a nonaluminum surface, and one region of the electrolyte is oxygen-depleted relative to the region that is adjacent to the atmosphere. This may occur between the faying surfaces in a joint or in a stack or coil of aluminum sheet. The oxygen-depleted area is anodic and corrosion may occur there.

6.4. Intergranular Corrosion and Stress-Corrosion Cracking

In some environments and under some metallurgical conditions, aluminum alloys are susceptible to *intergranular attack.* If the alloy-temper is not susceptible to stress-corrosion cracking, then intergranular corrosion tends to decrease in time, and its effect on strength for a given depth of attack is about the same as pitting corrosion. For *stress-corrosion cracking* (SCC) to proceed, four conditions must be met: (1) a metallurgical structure susceptible to SCC, (2) an environment that can cause SCC, (3) a sustained tensile stress, and (4) time. Only the alloys containing large amounts of soluble elements, e.g., copper, magnesium, silicon, and zinc, are susceptible. For most of the commercial alloys, SCC-resistance tempers have been developed, and effective protection systems have also been developed.

The electrochemical theory of SCC developed about 1940 dealt with SCC on the basis of continuous areas of anodic material in or along the grain boundaries [39]. These anodic areas are precipitates of an anodic phase in the grain boundary or anodic solid-solution zones adjacent to the grain boundary. In the Al – Cu alloys the solute-depleted zones are most anodic. In the Al – Mg alloys the precipitate Al_8Mg_5 is the most anodic. The theory is now seen to be incomplete or inadequate and work continues, especially on the possibility of hydrogen playing a significant role [40]. A most promising elastic-plastic fracture mechanics model was developed. It deals with stress-corrosion cracking damage and the strength and toughness of the material [41].

6.5. Exfoliation Corrosion

Exfoliation corrosion, also known as lamellar layer or stratified corrosion, proceeds along paths approximately parallel to the surface. The corrosion product is voluminous, causing delamination and swelling. It is usually associated with a metallurgical structure consisting of long, flat grains and probably results from aligned intergranular or subgrain-boundary precipitates or from layers of slightly different composition. Metallurgical practices to prevent or minimize these susceptible structures have been developed.

6.6. Ratings for Resistance to Corrosion

From the vast amount of detailed information available, ratings of resistance to ordinary corrosion and to stress-corrosion cracking have been compiled for a number of alloy-tempers (Tables 14, 15, and 20, also see [8]). These ratings are useful, but the selection of the optimum alloy-temper-product for a particular application is many faceted and requires expertise.

The rating system for resistance to stress-corrosion cracking has been expanded to acknowledge that susceptibility depends not only on alloy-temper but also on product form and the direction of sustained stress with respect to the metallurgical grain structure. Generally, susceptibility is lowest when the stress is longitudinal, i.e., parallel to the major direction of metal flow. Susceptibility can be higher when stress is normal to the major flow and parallel to the minor flow (long transverse). Susceptibility is highest when the stress direction is normal to both major and minor flows (short transverse) [8, pp. 213 – 14].

6.7. Corrosion Prevention

Methods of preventing corrosion are well developed [4, Chap. 7]. The alloy-temper should be selected for suitability in the service environment. Corrosion risks should be minimized by proper design of the part and the equipment in which it serves. Suitable protective finishes, e.g., conversion coatings, anodized film, organic paints, and films, should be chosen. In some cases cathodic protection can be used.

7. Major Markets [25], [42]

By far the greatest part of aluminum shipments is in the form of aluminum alloys, and production of primary aluminum and consumption of aluminum are the best indicators of the importance of aluminum alloys.

World production of primary aluminum is summarized in Table 38, and per capita consumption of aluminum in selected countries is summarized in Table 39 (see page after next).

The major markets for aluminum products are shown in terms of use by major industries in the United States in Table 40 (see page after next). To eliminate duplication, the figures exclude intra-industry shipments for further fabrication.

1. Aluminum Sulfate and Alums

1.1. Aluminum Sulfate

Aluminum sulfate is the second most important industrial compound of aluminum, after aluminum oxide. Aluminum sulfate was first used in Paris in 1844 to replace potassium alum. Today, it has taken over almost all areas of application that potassium alum originally had.

1.1.1. Properties

Aluminum sulfate is almost insoluble in anhydrous alcohol but readily soluble in water; aqueous solutions are acidic. Literature data on solubility and the structure of the precipitate in water differ markedly and should be used with caution (see Table 1). Previously, $Al_2(SO_4)_3 \cdot 18\ H_2O$ was thought to crystallize from aqueous solution under normal conditions (20 °C, 1 bar). This is now doubted, because such factors as hydrolysis, oversaturation, shifts in equilibrium, and, particularly, poor crystal formation make definitive characterization difficult [5]. The common form of aluminum sulfate, generally considered to be $Al_2(SO_4)_3 \cdot 18\ H_2O$ [*7784-31-8*], occurs in nature as alunogen (hair salt) and can be crystallized from hydrochloric acid solution as microscopically small, white needles. However, some researchers ascribe a hydrate water content of 17 mol to this form of aluminum sulfate [6]. A hydrate containing 27 mol of water can be prepared readily and in high purity [1]. Other well-defined aluminum sulfates contain 16, 10, and 6 mol of water. A total of 39 basic and 3 acidic aluminum sulfates, as well as 13 different hydrates of the neutral salt, are described in the literature [7]. The existence of aluminum

sulfates with 14, 13, 12, 9, 7, 4, 2, and 1 mol of water can be concluded from the vapor-pressure curves and the dehydration curves of the $Al_2(SO_4)_3 - H_2O$ and $Al_2(SO_4)_3 - Al(OH)_3 - H_2O$ systems [8, 9].

In industrial practice, the hydrate water content is unimportant because "crystalline" aluminum sulfate is a ground, microcrystalline solid with variable water content, which is obtained from a melt. The desired Al_2O_3 content is adjusted within certain limits by heating. At a temperature above 340 °C, anhydrous aluminum sulfate [*10043-01-3*] is formed, a white powder, ϱ 2.71 g/cm^3, that decomposes above 770 °C to aluminum oxide [9].

1.1.2. Production

In Germany and most European countries, aluminum sulfate is produced on a large scale only from aluminum hydroxide and sulfuric acid by the Giulini process. In this process, aluminum sulfate is obtained relatively easily with high purity. Production by the action of sulfuric acid on aluminum-containing ores (clays and bauxite with high silicon and low iron content, e.g., bauxite with $SiO_2 > 5$ %, Fe_2O_3 ca. 1 %) is still important in some countries.

Giulini Process [10]**.** The Giulini method for producing various grades of aluminum sulfate, containing between 8 and 23 % Al_2O_3, is shown schematically in Figure 1.

A pressure-resistant, stirred vessel (a) is filled with aluminum hydroxide (moist or dry). The calculated quantity of warm sulfuric acid is added from a preheater, and the mixture is stirred. In calculating the sulfuric acid concentration required to obtain an SO_3 content of ca. 1 % below stoichiometric, all process steps involving the introduction or the removal of water must be accounted for. Generally, acid of density 1.6 g/cm^3 is used. The reaction starts after 60 – 300 s and is complete after 10 – 12 min. The heat of reaction causes the temperature to rise to ca. 170 °C, while the pressure rises to 5 – 6 bar. The mixture must not be stirred for more than 1 h because otherwise the aluminum sulfate can hydrolyze to give insoluble basic aluminum sulfate and strongly acidic sulfate melt. An autoclave unit allowing batches of 2.5 t can produce ca. 50 t of aluminum sulfate in a 10-h shift.

The melt is led into a copper container where it is concentrated by flash evaporation (b). From the evaporator, the melt is sucked into a well-isolated vacuum tank (c), which is evacuated to the vapor pressure of the aluminum sulfate melt. This vacuum cooling avoids incrustation of the heat exchanger surfaces.

The melt falls from the vacuum container into the mixer, where it is seeded at 85 °C with 1 – 2 % aluminum sulfate powder. The pulp-like product reaches the "crystallization belt," a smooth, heat-resistant, trough-form rubber conveyor belt (e), and crystallizes there in ca. 30 min. Because of the high heat of crystallization, the material has a temperature of ca. 90 °C and cannot be broken to fine size in one step (f). It passes over air-cooled conveyor belts until it has cooled to 40 °C, after which it is ground (h) and sieved (i). The goods are filled (j) into paper or jute sacks or transported loose in silo cars. Aluminum sulfate with 17.2 % Al_2O_3 produced in this way contains only 0.01 % insoluble material; therefore, digestion of the aluminum hydroxide is almost complete. For transportation as a solution the Al_2O_3 content is adjusted to ca. 8 % to avoid crystallization during transport.

Production from Bauxite. Finely ground bauxite (for example, 60 % Al_2O_3, 1.5 % Fe_2O_3, 1.6 % TiO_2, 3.0 % SiO_2, 32 % H_2O) also can be used as starting material. In this case, 3 mol H_2SO_4 are charged onto 1 mol Al_2O_3. The Fe_2O_3 component in bauxite is disregarded because the Al_2O_3 is only 97 – 98 % digested and therefore sufficient sulfuric acid is available for production of aluminum sulfate containing 17.5 % Al_2O_3. The aluminum sulfate obtained by digestion of bauxite contains ca. 0.5 % Fe_2O_3 and ca. 2.2 % insoluble residue.

Production from Less Pure Starting Materials. Acid digestion of predominately silicon-rich raw materials gives a solution of aluminum sulfate. The purity depends on the process and starting materials. Iron, which strongly interferes, is precipitated with calcium hexacyanoferrate (II) as Berlin blue (iron hexacyanoferrate (II)), with calcium sulfide as iron sulfide, or by hydrolysis as basic iron sulfate. For details, see [11]. The clear solution is de-

canted and sold as a liquid or concentrated to 61.5 °Bé, allowed to solidify, and milled. The final product, which contains ca. 0.5 % Fe_2O_3 and 0.1 % insoluble material, is the *technical grade.* In addition, there is an *iron-free grade* having an Fe_2O_3 content of ca. 0.005 %.

The *Kretzschmar* process is used to produce very pure, iron-free aluminum sulfate by digestion of clay (for example, 40 – 43 % Al_2O_3, 53 – 56 % SiO_2, 2 – 4 % Fe_2O_3) with sulfuric acid. The greater part of the impurities is removed and crystals are separated from the solution by stirring. The formation of colloids is avoided by using vacuum apparatus. Pure, large crystals of $Al_2(SO_4)_3 \cdot 18\,H_2O$ (15.3 % Al_2O_3) can be separated easily from the impure mother liquor by

centrifuging [12]. The residue from the digestion process (SiO_2) can be converted with lime to calcium hydrosilicate, which increases the hardness of and also plasticizes lime mortar.

In a process developed by the U.S. Bureau of Mines, alcohol is used to reduce the viscosity of the oversaturated aluminum sulfate mother liquor [13].

Olin Mathieson Chemical Corp. developed an economical process for producing high-quality aluminum sulfate from the clay or waste shale of coal mines. Large crystals (1.5 – 3 mm) with iron contents of less than 0.03 % are produced in a patented crystallizer [14]. A process for producing aluminum sulfate from alum-containing ores is given in [15].

Aluminum sulfate is produced from waste "red mud" (from the aluminum oxide industry) by suspending the mud in water and passing sulfur dioxide through the suspension until pH 2 is reached. After filtration and removal of the sulfur dioxide in vacuo to give a pH of 4.5 – 5.0, $Al(OH)SO_3$ and $SiO_2 \cdot n\,H_2O$ precipitate. The precipitate is filtered and treated with sulfuric acid, whereby aluminum sulfate dissolves. [16].

Commercial Grades. Whereas $Al_2(SO_4)_3 \cdot 18\,H_2O$ theoretically contains 15.3 % Al_2O_3, commercial grades of aluminum sulfate contain 14 – 15 %, 15 – 16 %, 17 – 18 %, 18 %, or 22 – 23 % Al_2O_3 (Table 2). Generally, the aluminum sulfate containing 17 – 18 % Al_2O_3 (water-soluble aluminum content, calculated as Al_2O_3) is used most frequently. The calculated hydrate water content of this aluminum sulfate is 13 mol. The commercial grade containing 17 – 18 % Al_2O_3 is delivered also with various special qualities, such as low arsenic or low iron content.

The *basicity* of the product is defined as the excess in Al_2O_3 over the stoichiometric SO_3 : Al_2O_3 ratio. The 17 – 18 % Al_2O_3 grade has a basicity of 0.1 – 1 %, i.e., the Al_2O_3 content exceeds the stoichiometric amount by 0.1 – 1 %. Occasionally, the term "basicity" is defined as the ratio % SO_3 to % Al_2O_3. For commercial aluminum sulfate, this ratio is ca. 2.30, whereas the theoretical value is 2.35. This weakly basic aluminum sulfate has the advantage that it is less hygroscopic and therefore hardly affects either the metal parts of the apparatus during use or paper sacks during transport. Also, free acid damages cellulose fibers in the paper industry.

1.1.3. Uses

About two thirds of the total aluminum sulfate production is used for treating water. About one half of the total production goes into the paper industry (paper sizing, pH adjustment, wastewater purification) [17, p. 246].

Paper Industry. Aluminum sulfate is used for precipitating and fixing sizing agents, wet-strength agents, and basic dyes; for improving retention; for dispersing resin particles that stick together and block sieves; as the starting material of a high-quality slip for coating glossy paper (satin white); and for the production of lake dyes and wallpaper. For an overview of uses in newspaper factories, see [18]; for a detailed discussion on the importance of aluminum sulfate in paper production, see [5]. Aluminum sulfate with more than 0.2 % Fe_2O_3 gives paper a yellow tinge and cannot be used for good-quality white paper.

Water Purification. Aluminum sulfate is an important flocculating agent for purifying water [19]. The mechanism is as follows: Positively charged aluminum ions, which are hydrated or hydroxylated with water via numerous intermediate stages, neutralize the negative charge on the colloidal material in the water. As a result of mutual adsorption, the material flocculates, sediments at various rates, and finally settles as sludge after 15 – 150 min. To neutralize the hydrogen atoms formed on hydrolysis of aluminum sulfate, some carbonate hardness is consumed:

$$Al_2(SO_4)_3 + 6\,HCO_3^- \rightarrow 2\,Al(OH)_3 + 6\,CO_2 + 3\,SO_4^{2-}$$

For 50 mg/L of the 17 – 18 % Al_2O_3 grade 0.25 mmol/L of carbonate hardness (based on alkaline-earth ions) is consumed. Generally, 5 – 50 g aluminum sulfate is sufficient to purify 1 m^3 of water. An advantage of using aluminum sulfate is the lack of postflocculation, provided the correct amount is added. Disadvantages are the formation of free carbon dioxide, the increase of non-carbonate hardness, such as calcium sulfate, and the pH remaining between 5 and 7. If no natural bicarbonate hardness is

Table 2. Commercial grades of aluminum sulfate

Grade	Al_2O_3, wt %	Fe_2O_3, wt %	Insoluble material, wt %	Basicity *, %
8 % (solution)	8	0.004	–	1
14 – 15 %	14 – 15	0.006 – 0.008	0.04	0.1 – 1.0

* Defined in text

present, an alkaline substance that also has a dispersing effect, such as lime or sodium aluminate, must be added. Aluminum sulfate, used in combination with calcined leached clay, is suitable for binding mercury ions, for example, in sea water [20].

Other Uses. Aluminum sulfate with a very low iron content (below 0.01 %) is used as a mordant in dyeing; a higher iron content is unacceptable because this leads to color changes. Further uses are for pickling of seeds, deodorizing of mineral oils, tawing, and producing aluminum hydroxide gel employed, for example, as a filler for synthetic rubber. Aluminum sulfate has some importance also as a catalyst support. Finally, it is the starting material for almost all other aluminum compounds.

Production and Capacity Data. Aluminum sulfate production in the USA was 1 168 000 t in 1980 and 1 075 000 t in 1982 [21]; that in Japan was 757 000 t in 1980 [22]. The main U.S. producer of aluminum sulfate is Allied Corp. The main Japanese producers are Nikkei Kako Co. and Scintoma Aluminum Smelting Co.

1.2. Alums

Historical Aspects. *Alumen*, from which the word alum is derived, was known to the ancient Greeks and Romans as an astringent and also as a mordant in dyeing wool. Alum was employed in processing skins, for embalming animal and human corpses, and for fireproofing wood. However, what was known at first as alum was not a defined substance but referred to both alum-containing minerals and mixtures of alum with iron vitriol. Paracelsus was the first to distinguish true alum from iron vitriol. In the years 1776 – 1798, Chaptal and Vauquelin established that alum was a double salt of potassium and aluminum sulfates and that the potassium ions could be replaced by ammonium ions. The raw material of the ancient alum industry was alum stone (alunite) or alum shale. Alum stone contains all components of the alum in the correct ratios and is processed by roasting and leaching. Roasting, aging for several years, and leaching of alum shale gave an aluminum solution from which the alum was precipitated with alkali. The alum industry played an important role during the whole of the Middle Ages.

The industrial production of the alums ceased to have particular importance when it became possible to produce aluminum sulfate economically in high purity, because only the aluminum content is of practical importance. Most of the alum production methods now have only limited, partly only historical, interest. Clay and other alkali-containing silicates, particularly bauxite, were used as raw materials and were digested using alkali or acid. Today, alums are produced only from aluminum hydroxide, which is obtained by the Bayer process from bauxite (→ Aluminum Oxide).

General Properties. Alums are crystalline double salts of the general formula (cation 1)$^+$ (cation 2)$^{3+}$ (anion^{2-})$_2$ · 12 H_2O. The most useful alums are those with trivalent aluminum cations and sulfate anions, $M^+Al^{3+}(SO_4^{2-})_2 \cdot 12\ H_2O$. The individual components of the alum can be replaced, retaining both the regular crystalline form and the hydrate water. Alums with the following trivalent metals are known: iron, chromium, cobalt, manganese, titanium, vanadium, gallium, indium, scandium, rhodium, and iridium. The monovalent component can be an alkali metal, or it can be ammonium, alkylammonium, arylammonium, or thallium. The existence of a lithium alum is uncer-

tain. Known combinations include potassium–aluminum, cesium–aluminum, potassium–chromium, and hydroxyammonium–aluminum. A selenate alum also is known: $KAl(SeO_4)_2 \cdot 12\ H_2O$.

All alums crystallize in strongly refracting octahedra or cubes [1]. They have an astringent taste and rot-proofing, protein-precipitating properties.

In *aqueous solution*, alums show all the chemical properties that their components show separately. Physical properties, such as color, electrical conductivity, and freezing-point lowering, are the sum of the properties of the components, provided the solutions are very dilute. At higher concentrations, complexes, such as $[Al(SO_4)_2 \cdot (H_2O)_2]^-$, are formed. The solubilities of the alums in water decrease from sodium to cesium (see Table 3). On heating, the alums lose their water of crystallization either partially or completely. However, part of the water is taken up again at normal temperature and humidity.

1.2.1. Potassium Aluminum Sulfate

Potassium aluminum sulfate [*7784-24-9*], known as potassium alum, $KAl(SO_4)_2 \cdot 12\ H_2O$, ϱ 1.75 g/cm^3, M_r 474.4, and ammonium aluminum sulfate are the aluminum compounds known longest. Potassium alum occurs in nature as efflorescence on alum shale and in volcanic areas on trachyte and lava as feather alum.

Potassium alum crystallizes in large, colorless, transparent octahedra, which melt at 92.5 °C in their own water of crystallization. The hardness of the crystals on the Mohs scale is 2. The octahedra absorb long-wavelength IR radiation almost completely, but are transparent to visible light. Certain substances (hydroxides, carbonates, borates, carbamides, also metals and organic dyes) promote the formation of basic aluminum sulfate by binding free sulfuric acid in the mother liquor. Under these conditions, the cubic form is favored (cubic or Roman alum).

Potassium alum is stable in air of normal humidity. Dehydration does not begin below 30 °C, but at 65 °C nine moles of water are lost. Literature data on the dehydration are contradictory. Investigations on thermal decomposition are given in [23]. According to these results, K_2SO_4, γ-Al_2O_3, and 3 $K_2SO_4 \cdot Al_2(SO_4)_3$ form at 780 °C, whereas K_2SO_4, α-Al_2O_3, and $K_2O \cdot 12\ Al_2O_3$ are produced at 1400 °C. When heated above its melting point, potassium alum dehydrates, forming calcined alum (alum ustum), KAl $(SO_4)_2$ [*10043-67-1*]. At red heat, SO_3 is released.

Potassium alum is soluble in dilute acid but almost insoluble in anhydrous alcohol, acetone, and methyl acetate. Because of the marked increase in solubility in water with temperature, potassium alum can be purified more easily than other aluminum salts by recrystallization and, in particular, can be freed from iron sulfate. Mixed crystals form readily with ammonium sulfate.

Basic potassium aluminum sulfate, $K[Al(OH)_2]_3(SO_4)_2 \cdot 3/2\ H_2O$, occurs in nature as löwigite. The compound is made synthetically as a rather insoluble, amorphous powder by heating aluminum sulfate, water, and an excess of potassium sulfate or by heating potassium alum with water in the ratio 1 : 4 to 200 °C [24]. Another basic potassium aluminum sulfate, $K[Al_3(OH)_6(SO_4)_2]$ [*1302-91-6*], containing less water, is the alum stone (alunite) occurring in nature.

Production. Aluminum hydroxide (wet hydrate; Al_2O_3 ca. 57 %, Fe_2O_3 0.016 – 0.023 %, H_2O 42.5 %) and sulfuric acid ($\varrho \approx 1.6$ g/cm^3; Fe_2O_3 0.020 – 0.040 g/L) react in a stirred, corrosion-resistant pressure boiler at 5 – 6 bar to form aluminum sulfate as shown in Figure 1. The aluminum sulfate melt is then led, with release of pressure, into a copper container. Here, a stoichiometric quantity of potassium sulfate (as chloride-free as possible) is added. The solution is heated to ca. 100 °C for 2 – 3 h and adjusted to 40 – 44 °Bé with mother liquor. After filtration from insoluble material, the alum melt is left in crystallization boxes for 10 days, after which the alum is removed in blocks. The product obtained in this way contains < 0.001 % Fe_2O_3, 0.001 – 0.004 % chloride, and < 0.01 % insoluble material.

For the production of *alum crystals*, the alum melt is brought into a stirred crystallization bath, where it is cooled to ca. 40 °C by air bubbles. The pulp is then separated from the mother liquor by centrifuging and washed. The mother liquor is collected and returned to the copper container. The potassium alum is dried at 50 –

Table 3. Solubility of some aluminum alums as a function of temperature (grams of anhydrous salt per 100 g water)

60 °C. The salt, which forms lustrous crystals, is sieved and packed in paper bags that are lined with polyethylene.

A process for obtaining potassium alum from alum-containing ores is given in [15], and the production of basic potassium and sodium alums from synthetic alum is described in [25].

Uses. As already mentioned, the industrial importance of potassium alum has declined considerably. However, it is still employed in tawing skins, as a mordant in dyeing, and as a coagulating agent for latex. Because of its astringent and protein-precipitating properties, potassium alum is used in the pharmaceutical and cosmetics industries. The use of potassium alum as a styptic pencil, because of its blood-stanching property, is very widespread and popular. The most important application today is in the gypsum industry, which employs potassium alum as hardening agent and setting accelerator for the production of marble cement and alabaster plaster. However, for purifying water and sizing paper, potassium alum has been replaced completely by aluminum sulfate. In the paper industry, aluminum sulfate is designated traditionally, although incorrectly, as an alum.

1.2.2. Ammonium Aluminum Sulfate

Ammonium aluminum sulfate [*7784-26-1*], also called ammonium alum, $NH_4Al(SO_4)_2 \cdot 12\ H_2O$, M_r 453.33, ϱ 1.64 g/cm^3, *mp* 93.5 °C, occurs in nature as shermigite. Crystals doped with other alums show birefringence. The solubility of ammonium alum in water is similar to that of potassium alum, with which it forms a continuous series of mixed crystals. Ammonium alum is slightly soluble in dilute acids and glycerol but insoluble in absolute alcohol. In aqueous solution, ammonium alum is neutral.

Data on loss of water on heating are in disagreement. Gel'Perin and Chebotkevich [26] have reported that water of crystallization is released in three stages: first to give the hydrate with 21 mol water, then to that with 3 mol water, and finally to the anhydrous product, so that it is in fact more correct to formulate ammonium alum with 24 mol water. Above 193 °C, decomposition with the release of ammonia begins. On glowing above 1000 °C, sulfur trioxide is lost, leaving an aluminum oxide residue.

Production. Ammonium alum is made mainly by dissolving aluminum hydroxide in sulfuric acid and adding ammonium sulfate but sometimes by the reaction of ammonia gas with aluminum sulfate and sulfuric acid. The procedure is analogous to the potassium alum process. To obtain a quality particularly low in iron oxide or other metal oxides (< 0.0001 % Fe_2O_3; normal quality ca. 0.001 % Fe_2O_3), as is required for production of synthetic gems, very pure starting materials must be used. Ammonium alum occurs as an intermediate in the "aloton" process, which operates in a sulfuric acid medium. This process had some importance prior to 1945 in Germany and the United States for aluminum hydroxide and aluminum oxide production (→ Aluminum Oxide)

Uses. In Europe, ammonium alum is not used in large quantities. Applications include those in dressing furs in tanning, in the production of very fine aluminum oxide particles for polishing metallographic surfaces, and, in some countries outside Europe, as a disinfectant. In the United States, ammonium alum is important as an additive in baking powder; ca. 500 t/a are produced for this purpose. More recently, ammonium alum has gained considerable importance as starting material for the production of the finely powdered, loose aluminum oxide of high purity that is required for synthesizing corundum gems, such as rubies and sapphires. This quality

of aluminum oxide is made by heating ammonium alum (or ammonium aluminum selenate alum) to 1000 °C.

1.2.3. Sodium Aluminum Sulfate

Sodium aluminum sulfate [*7784-28-3*], sodium alum, $NaAl(SO_4)_2 \cdot 12\ H_2O$, melts at 61 °C in its water of crystallization. In nature, it occurs as the mineral mendozite. Again, the data on thermal dehydration disagree. Sodium alum is insoluble in absolute alcohol but is much more soluble in water than all other alums. Alum powder (very fine crystalline form) is not available commercially. These two facts make it difficult to obtain sodium alum free from iron. Because of this and also because of its strong tendency to age, sodium alum has never gained the same importance as the other alums. In Europe, its use has been abandoned. In the United States, however, sodium alum is still utilized in relatively large quantities (ca. 3000 t/a) in baking powder.

Production. In the United States, sodium alum is produced by adding a clear solution of sodium sulfate to aluminum sulfate. After dilution to 30 °Bé and subsequent heating, a sludge of potassium sulfate, sodium silicate, and caustic soda is added to improve the purity of the product. The mixture is pumped into a stirred vessel, where it is mixed for several hours. During this stage, the ratio of aluminum sulfate to sodium sulfate is adjusted to the stoichiometric amount. Afterwards, the melt is pumped into an evaporator and concentrated to such an extent that it solidifies to a hard cake on pouring into a cooling tank. This sodium alum cake is then heated and finally ground to the desired size (99 % through a sieve of 100 mesh) [17, p. 250].

2. Aluminates

Only the aluminates of barium and sodium have importance in industry. Aluminates occur also in cement and in spinels.

2.1. Sodium Aluminate

Sodium aluminate [*1302-42-7*] is an important commercial inorganic chemical. It functions as an effective source of aluminum hydroxide for many industrial and technical applications. Commercial grades of sodium aluminate are available in solid and liquid forms. Pure sodium aluminate (anhydrous) is a white crystalline solid having a formula variously given as $NaAlO_2$, $Na_2O \cdot Al_2O_3$, or $Na_2Al_2O_4$. Commercial grades, however, always contain more than the stoichiometric amount of Na_2O, the excess being on the order of 1.05 to 1.50 times the formula requirement. Hydrated forms of sodium aluminate are crystallized from concentrated solutions.

Sodium aluminate has no defined melting point; it softens above 1700 °C when sodium begins to evaporate slowly, leaving aluminum oxide.

Production. The chief commercial process for the manufacture of sodium aluminate is the dissolution of aluminum hydroxides in sodium hydroxide solution. Aluminum trihydroxide (gibbsite) from the Bayer process (→ Aluminum Oxide) can be dissolved in 10 – 30 % aqueous NaOH solution at a temperature near the boiling point.

The use of more concentrated NaOH solutions leads to a semisolid product. The process is carried out in steam-heated vessels of nickel or steel, and the aluminum hydroxide is boiled with ca. 50 % aqueous sodium hydroxide until a pulp forms. After this is poured into a tank and cooled, a solid mass containing about 70 % $NaAlO_2$ is formed. After being crushed, this product is dehydrated in a rotary oven heated either directly or indirectly by burning hydrogen. The resulting product contains ca. 90 % $NaAlO_2$ and 1 % water, together with 1 % free NaOH. The solubility of the salt produced in this way depends strongly on how much excess sodium hydroxide is used.

Alternatively, bauxite can be used directly as the alumina source. Bauxites containing gibbsite are extracted at 150 °C and 5 bar, whereas boehmite containing bauxite requires higher temperatures (230 °C) and pressures. The sodium aluminate solution obtained from the digestion process is separated from any impurities and then concentrated to the commercial liquid grade by evaporation. The solid product is obtained by drying the liquid.

The sinter method also has been used to produce sodium aluminate. By sintering sodium carbonate directly with Bayer aluminum trihydroxide in rotary sintering kilns at 1000 °C, an essentially anhydrous product can be obtained. When sintering bauxite, it is essential to leach the sinter mass with water and separate the impurities.

Uses. The major use of sodium aluminate is for water treatment, including both potable and industrial waters. Sodium aluminate is used as an adjunct to water softening systems, as a coagulant aid to improve flocculation, and for removing dissolved silica. Sodium aluminate dissolves in water to give a solution that has a pH value of 8. The aluminum hydroxide that precipitates from this solution has excellent flocculation properties and coagulates other impurities present in the water. Depending on the impurities, the conditions of precipitation can be improved by adding aluminum sulfate [27].

In *construction technology*, sodium aluminate is employed to accelerate the solidification of concrete, mainly when working during frost, under water, and in humid soil (see Table 4). Compared to calcium chloride, which acts in a similar manner, sodium aluminate has the advantage of greater setting acceleration at low water-to-cement ratios [28]. Because it does not attack the reinforcing metals, it can be used for work with steel-reinforced concrete. Too rapid setting can cause cracks in the concrete, affecting the final strength of the building. By adding substances such as oxoacids [29], sugar, naphthene [30], K_2CO_3, or Na_2SO_4 [31] the final strength increases without affecting the setting rate significantly. Sodium aluminate increases the resistance of mortar to water, alkali, and acid. For the production of expanded concrete, sodium aluminate serves to activate nitrogen-releasing substances [32]. To stabilize foam formation in the production of light refractory bricks, up to 5 % (relative to the total dry mass) sodium aluminate is added.

Increasingly, sodium aluminate is being used for the production of *synthetic zeolites*, used as catalyst supports or as catalysts [33 – 36] and as adsorbents. Sodium aluminate is one of the principal sources of *alumina* of the preparation of alumina adsorbents and catalysts.

Table 4. Acceleration of setting by sodium aluminate in a mixture of 6 parts sand, 2 parts concrete, and 1 part water

% $NaAlO_2$ in concrete	Setting started	Setting completed
0	4 h 30 min	6 h
1	30 min	1 h 40 min
1.5	15 min	30 min
2	10 min	15 min
10	instantly	

In the *paper industry*, sodium aluminate increases the opacity [37], retention of fibers and filling materials [38], and the paper strength [39]. Also, it stabilizes the pH value of the water circulation [40] and increases the dispersion stability of titanium dioxide [41].

Another application of sodium aluminate is as a *pickle* to protect metallic surfaces (copper [42], aluminum [43], among others). This effect is based on the formation of a thin, very firmly adhering layer of aluminum hydroxide or, after heat treatment, of aluminum oxide on the surface, which does not affect the metallic luster. In the *enamel industry*, sodium aluminate is added to enamel mixtures to achieve low-melting covers [44].

Further applications of sodium aluminate are in lithography for the production of printing inks [45] and print forms [46], in the detergent and varnish industries, in the production of water-insoluble floor waxes [47], as a dispersion agent for production of high-purity asbestos [48], as an additive to drilling fluids [49], and in the textile industry as a mordant in dyeing and in printing cloth. Many other uses of sodium aluminate have been reported. These include inhibition of glass etching by alkaline solutions; protection of steel surface during galvanizing; improving dyeing, antipiling, and antistatic properties of polyester synthetic fibers; as an additive to foundry sand molds and cores; and as a binder in the ceramics industry.

2.2. Barium Aluminates

The industrially important barium aluminates are $BaO \cdot 6\ Al_2O_3$ [*12254-17-0*], *mp* 1915 °C; $BaO \cdot Al_2O_3$ [*12004-04-5*], *mp* 1815 °C; and $3\ BaO \cdot Al_2O_3$ [*12004-05-6*], *mp* 1425 °C [50]. The first two crystallize hexagonally.

Barium aluminates are produced by melting bauxite with coal and barite. Leaching the melt gives a solution of barium aluminate, from

which the salt is obtained by evaporation. Very pure barium aluminates can be produced by sintering mixtures of aluminum oxide with barium carbonate. All barium aluminates, including such hydrated compounds as $BaO \cdot Al_2O_3 \cdot 4\,H_2O$, $2\,BaO \cdot Al_2O_3 \cdot 5\,H_2O$, $BaO \cdot Al_2O_3 \cdot 7\,H_2O$, and $7\,BaO \cdot 6\,Al_2O_3 \cdot 36\,H_2O$, hydrolyze in water, forming hydrargillite (gibbsite), $Al(OH)_3$, and relatively soluble barium hydroxide.

Barium aluminate is used for purifying water because the Ba^{2+} ion precipitates both the sulfates and the carbonates, whereas the aluminate ions form insoluble calcium aluminate. A further use of barium aluminates is as a special cement, for example, as binding agent for the production of high-temperature refractories, and in the production of radiation shields [51].

3. Aluminum Alkoxides

Aluminum alkoxides (alcoholates) are solid or liquid compounds of covalent character. They are readily soluble in hydrocarbons, but sparingly soluble in alcohols. Hydrolysis with water occurs readily, giving aluminum hydroxide and the corresponding alcohol. For a general review of aluminum alkoxides, see [52]. Industrially, only the isopropoxide (isopropylate) and *sec*-butoxide (*sec*-butylate) are important. These compounds are used to adjust the viscosity of varnishes, to impregnate textiles, as intermediates in the production of pharmaceuticals, and as antitranspirants in cosmetics. In the industrial production of ketones and aldehydes, aluminum alkoxides are employed as reducing agents (Meerwein-Ponndorf reaction).

Aluminum isopropoxide [*555-31-7*], $Al(OCH(CH_3)_2)_3$, is a white solid, M_r 204.25, *mp* 118 °C, *bp* 125 – 130 °C at 533 Pa, d_4^{20} 1.0346, flash point 26 °C. It is usually produced by direct reaction of aluminum and isopropyl alcohol in the presence of mercury(II) chloride catalyst. In a later version of the process [53], the alcohol was heated under reflux in a column filled with aluminum chips; no catalyst was required and nearly quantitative conversion was obtained. The alkoxide can be purified by distillation. In an alternative production method, excess isopropyl alcohol is added to a solution of aluminum chloride in benzene; the hydrogen chloride formed is removed by introducing dry ammonia into the reactor and filtering off the ammonium chloride that precipitates.

Aluminum *sec*-butoxide [*2269-22-9*], $Al(OC_4H_9)_3$, is a colorless liquid, M_r 246.3, *bp* 180 °C at 533 Pa, d_4^{20} 0.9671, flash point 26 °C, and is produced in a manner similar to aluminum isopropoxide.

4. Aluminum Chloride

4.1. Anhydrous Aluminum Chloride

Oerstedt first prepared anhydrous aluminum chloride [*7446-70-0*] in 1825 by the reaction of chlorine gas with a mixture of alumina and carbon. This compound has acquired great significance in organic chemistry as a catalyst, particularly for Friedel-Crafts syntheses and allied reactions for the production of alkylated aromatics, dyestuffs, pharmaceuticals, and perfumery chemicals. For general literature, see [1] and [54].

4.1.1. Properties

Physical Properties. In the solid and gas phases at temperatures up to 400 °C, aluminum chloride is present as the dimer, Al_2Cl_6. Dissociation of the dimer progresses with rising temperature and is quantitative above 800 °C. Solid aluminum chloride crystallizes to form a monoclinic layer lattice. Pure aluminum chloride is white, but the commercial product usually has a yellowish or grayish tinge because of small amounts of iron chloride or aluminum impurities. Physical properties of anhydrous aluminum chloride [55]:

M_r	133.34
ϱ at 25 °C	2.44 g/cm^3
Sublimation temperature at 101.3 kPa	181.2 °C
Triple point, at 233 kPa	192.5 °C
Heat of formation at 25 °C	–705.63 ± 0.84 kJ/mol
Heat of sublimation of dimer at 25 °C	115.73 ± 2.30 kJ/mol
Heat of fusion	35.35 ± 0.84 kJ/mol
Heat of solution at 20 °C	–325.1 kJ/mol

Chemical Properties. Anhydrous aluminum chloride reacts extremely violently with water, evolving hydrogen chloride. The hexahydrate [*7784-13-6*], $AlCl_3 \cdot 6\,H_2O$, M_r 241.44, is formed in this reaction. In aqueous solution, aluminum chloride is partially hydrolyzed to hydrochloric acid and aluminum oxychloride, AlClO [*13596-11-7*]. For this reason, anhydrous aluminum chloride cannot be obtained by concentrating the solution and calcining the hydrate. When aluminum chloride is heated with γ-alumina, aluminum oxychloride, AlClO, forms, but this reaction goes in the reverse direction at temperatures above 700 °C:

$$AlCl_3 + Al_2O_3 \rightleftharpoons 3\,AlClO$$

If aluminum chloride vapor is passed at 1000 °C under reduced pressure over molten aluminum, volatile aluminum monochloride [*13595-81-8*], AlCl, is formed, but this decomposes immediately into the elements in cooler zones of the reactor. This method has been adopted for purifying aluminum.

Reaction between aluminum chloride and other metal halides, such as $CaCl_2$, $CrCl_3$, and $FeCl_3$, gives mixed halides. Eutectic melts with other metal chlorides are of industrial significance, for example, that with sodium chloride is used as a solvent in chlorination reactions.

Anhydrous aluminum chloride dissolves readily in polar organic solvents. As a Lewis acid it forms addition compounds with numerous electron donors, such as hydrogen chloride, hydrogen sulfide, sulfur dioxide, sulfur tetrachloride, phosphorus trichloride, ethers, esters, amines, and alcohols.

4.1.2. Production

The starting materials are either aluminum or pure aluminum oxide. Bauxite now has no economic significance as a raw material because of the iron chloride always present in the product.

Chlorination of Aluminum [56]. Today, most anhydrous aluminum chloride is made by chlorinating aluminum.

Chlorine is passed through molten aluminum in ceramic-lined, tube-shaped reactors. The reaction is highly exothermic:

$$2\,Al\,(s) + 3\,Cl_2\,(g) \rightarrow Al_2Cl_6\,(s) \quad \Delta H^\circ = -1411\,kJ/mol$$

The temperature in the reactor is maintained at 670 – 850 °C by controlling the admission rates of chlorine and aluminum and by cooling the reactor walls with water. The aluminum usually is replenished in the form of lumps. The difficulty of controlling the large heat of reaction can be overcome also by dividing the process into a number of small units.

The aluminum chloride vapor leaving the reactors is passed through ceramic-lined tubes into large, air-cooled iron chambers. Solid aluminum chloride is withdrawn from the condenser walls at regular intervals, ground (insuring exclusion of moisture), and classified by sieving. Chlorine in the off-gas is removed by conventional methods, such as absorption in caustic soda solution.

Chlorination of Pure Aluminum Oxide. Chlorination of alumina is advantageous over the formerly widely used bauxite process (less reactor corrosion and higher-purity product), and at the same time it avoids the high raw material costs involved in metal chlorination [57].

Carbon monoxide and chlorine are partially converted to phosgene over an activated charcoal catalyst. The gaseous reaction mixture enters a brick-lined, fluidized-bed reactor, where it reacts with finely divided γ-alumina to yield aluminum chloride. The reaction is exothermic enough (ca. 300 kJ/mol, based on $AlCl_3$) to maintain the temperature at 500 – 600 °C without external heat. Consequently, the process permits large units, and the low reaction temperature insures that the brick lining has a long life.

The aluminum chloride vapor is filtered through a bed of coarse pumice chips, condensed, and further processed as described above. The off-gas contains chlorine, phosgene, and large amounts of carbon dioxide. The chlorine is removed by scrubbing, and the phosgene is hydrolyzed with water. Extremely pure aluminum chloride is obtained by resublimation from molten sodium aluminum chloride.

4.1.3. Quality Specifications and Analysis

Anhydrous aluminum chloride is ground and marketed as powder or granules. Aluminum is

usually determined by atomic spectrometry, the chloride by argentometry. The assay is 98 – 99 % $AlCl_3$. The main impurity is iron (0.05 wt % max. or 0.01 wt % for resublimed product). Sampling and analysis of anhydrous aluminum chloride must be carried out in an atmosphere of dry air or nitrogen.

4.1.4. Handling, Storage, and Transportation

Because of its corrosive and irritant action, anhydrous aluminum chloride is classified as a dangerous substance. National and international regulations must be observed, such as 67/548/EEC, the key European Economic Community directive dealing with the classification, packaging, and labeling of dangerous substances.

Handling. Goggles, gloves, and protective clothing must be worn when handling aluminum chloride. A fume cupboard or a respirator with filter type B/St against acid gases should be used. Because hydrogen chloride is evolved when aluminum chloride is exposed to water, any spills must be taken up dry, and only small, residual amounts can be washed away with plenty of water. Sodium bicarbonate or slaked lime should be used for neutralization.

Storage and Transportation. Aluminum chloride is dispatched in vented steel drums or in tank trucks or rail tankcars that can be emptied pneumatically with dry air or nitrogen (dew point below − 40 °C). Because the product tends to cake, it should not be stored for more than six months. International marine transportation is governed by the IMDG code, class 8, UN no. 1726. RID, ADR, ADNR: Class 8, no. 11b, Rn 801, 2801, 6801, respectively. EEC: Yellow Book 78/79, EG no. 013−003−00−7. UK: Blue Book, Corrosives & IMDG code E 8031. USA: DOT regulations, corrosive solid, CFR 49, 172.101.

4.1.5. Uses

Anhydrous aluminum chloride is an important *Friedel-Crafts catalyst* in the chemical and petrochemical industries [58, 59]. A principal application is the alkylation of benzene by alkyl halides to form alkylbenzenes that are consumed in the production of synthetic detergents, such as alkylbenzenesulfonates. Aluminum chloride also catalyzes the liquid-phase ethylation of benzene with ethylene to yield ethylbenzene, most of which is used in the production of styrene.

Ethyl chloride is produced mainly by the reaction of hydrochloric acid and ethylene in the presence of aluminum chloride; the consumption has significantly decreased because of the declining demand for tetraethyl lead as an antiknock additive.

In the dyestuffs industry, aluminum chloride is widely used as catalyst in the production of anthraquinone and its derivatives and of pigments, such as phthalocyanine green. A further application of aluminum chloride is as a finish for titanium dioxide pigments, which are in this way protected from oxidation by an oxide layer.

Until 1960, aluminum chloride was used extensively in petroleum refining for cracking and isomerization, but it has now been replaced by zeolite catalysts. It is still employed in reforming hydrocarbons, as a polymerization catalyst in the production of hydrocarbon resins, and for the production of butyl rubber.

It is a catalyst also in the production of compounds, such as aromatic aldehydes, ketones, and 2-phenyl-ethanol, used in fragrances. Other applications for anhydrous aluminum chloride include the production of aluminum borohydride, lithium aluminum hydride, as well as compounds of phosphorus and sulfur.

Most of these reactions with aluminum chloride produce a solution that is often used as a flocculating agent in the treatment of waste water.

Aluminum chloride also is an intermediate in the production of aluminum by the Alcoa smelting process [60] (→ Aluminum).

Data on the consumption of anhydrous aluminum chloride in the USA are given in Table 5.

Table 5. U.S. anhydrous aluminum chloride consumption in 1993 (not including the amounts consumed in the production of aluminum) [61]

Alkylate detergents	2200 t
Ethylbenzene	4000 t
Hydrocarbon resins	3900 t
Pharmaceuticals	4000 t
Titanium dioxide	2200 t
Miscellaneous	4900 t
Total	21200 t

4.2. Aluminum Chloride Hexahydrate

Properties. The white hydrate $AlCl_3 \cdot 6\ H_2O$ [*7784-13-6*], M_r 241.43, crystallizes hexagonally and dissolves exothermally in water (133 g hexahydrate per 100 g water at 20 °C) [62]. The solubility increases only slightly with temperature. The aqueous solutions are strongly acidic because the salt hydrolyzes. Hydrogen chloride is evolved on heating concentrated solutions. The structure of aqueous solutions of $AlCl_3 \cdot 6\ H_2O$ is discussed in [63].

Production and Uses. Aqueous solutions of $AlCl_3 \cdot 6\ H_2O$ can be obtained by dissolving aluminum hydroxide in hydrochloric acid: the hexahydrate crystallizes when hydrogen chloride passes into cold (about 20 °C) saturated solution. In this way, impurities, particularly iron (III) chloride, can be removed [62]. Aluminum chloride hexahydrate has only minor importance as such; for example, it is used for hardening photographic layers. However, it is of industrial importance as an intermediate in the production of aluminum oxide [64, 65].

4.3. Basic Aluminum Chlorides

Properties. Basic aluminum chlorides [*1327-41-9*], aluminum hydroxychlorides, aluminum chloride hydroxides, poly(aluminum hydroxychlorides), have the general formula $Al_2(OH)_{6-n}Cl_n \cdot x\ H_2O$. The individual compounds are best defined either by the molar ratio of aluminum to chloride ($2/n$) or by their basicity, defined as $(1 - n/6) \cdot 100\,\%$. Below a minimum water content, which depends on n, the compounds are unstable; they decompose to aluminum hydroxide and aluminum oxide on heating to above 80 °C, releasing water and hydrogen chloride. All basic aluminum chlorides with $n = 1 - 5$ can be isolated, and all are white, in some cases crystalline substances, partially soluble in the lower alcohols [66, 67], but readily soluble in water. For example, 170 g of the compound $Al_2(OH)_5Cl \cdot 2.5\ H_2O$ dissolves in 100 g water at 20 °C. However, the viscosity of the solution prevents further amounts from dissolving. The *electrical conductivities* of the aqueous solutions, shown in Figure 2, are characteristic of the basic aluminum chlorides.

Figure 2. Electrical conductivity of freshly prepared basic aluminum chloride solutions: ○) from Locron L (ca. 50 % aqueous solution of $Al_2(OH)_5Cl \cdot 2.5\ H_2O$) and hydrochloric acid at constant aluminum oxide concentration (11.5 %) and 20 °C; ▲) prepared directly from $AlCl_3 \cdot 6\ H_2O$

Aqueous solutions of basic aluminum chlorides are acidic because the compounds hydrolyze (see Table 6). The stability of the solutions depends on the basicity: compounds with aluminum to chloride molar ratios of ca. 0.5 : 1 to about 1.6 : 1, corresponding to basicities of ca. 30 – 75 %, decompose to give insoluble basic aluminum chloride at a rate that depends on the temperature and concentration of the solution [68]. On the other hand, compounds of basicity greater than 75 % are very stable in aqueous solution. For example, compounds with the approximate composition $Al_2(OH)_5Cl \cdot 2 - 3\ H_2O$ [*12042-91-0*] are so stable at concentrations > 50 % that no decomposition occurs, even on boiling for days.

Table 6. pH values of aqueous solutions of $Al_2(OH)_5Cl \cdot 2.5\ H_2O$ at 20 °C (mass fractions, w, in %)

w	pH
60	3.4
30	4.0
15	4.2
10	4.3
5	4.4
3	4.4

In contrast to the aluminum chlorides of low basicity (below 65 %), the compounds of high basicity (above 65 %) do not crystallize from their aqueous solutions, but form

glassy masses. When solutions in the basicity range 30 – 65 % are evaporated, the compound $Al_2(OH)_{3.7}Cl_{2.3} \cdot 6.05\ H_2O$ (basicity 62 %) always crystallizes [69]. On addition of alkali to basic aluminum chlorides, aluminum hydroxide precipitates. Hydrochloric acid converts all basic aluminum chlorides to the hexahydrate:

$$Al_2(OH)_5Cl + 5\ HCl + 7\ H_2O \rightarrow 2\ AlCl_3 \cdot 6\ H_2O$$

Chemical Structure. Basic aluminum chlorides have been known for a long time [1, p. 205], but only recently have investigations given significant insight into their chemical structures [70 – 73]. Basic aluminum chlorides are mixtures of complex compounds of various degrees of polymerization. Spectroscopic and kinetic investigations of the basic aluminum chlorides and of their solutions [70 – 73] lead to the conclusion that the complex ion $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ is present and is in equilibrium with its polymeric forms. Variations observed in the properties of these aqueous solutions such as viscosity and pH are caused by polymerization and depolymerization [74].

Analysis. Basic aluminum chlorides are so stable that the aluminum content can be determined only after decomposition of the complex ion [75, 76]. The usual procedure is to mix the solution containing aluminum with 60 % sulfuric acid and 0.1 M disodium ethylenediaminetetraacetate, followed by ca. 20 % sodium hydroxide. The pH is adjusted to 4.7 – 4.9 at 60 – 70 °C. After the solution is cooled to about 25 °C and buffer solution (acetic acid, ammonium acetate), acetone, and indicator (dithizone in ethanol) are added, the solution is backtitrated with 0.1 M zinc sulfate. One milliliter of 0.1 M disodium ethylenediaminetetraacetate is equivalent to 2.698 mg of aluminum.

Production. Basic aluminum chlorides are made by dissolving either aluminum hydroxide or metallic aluminum in hydrochloric acid. Aged aluminum hydroxide leads only to compounds of basicity up to 65 % [68]. To obtain aluminum chlorides of high basicity, freshly precipitated aluminum hydroxide [77] must be used. However, the preferred method is to dissolve aluminum in hydrochloric acid either thermally or electrochemically:

$$2\ Al + HCl + 5\ H_2O \rightarrow Al_2(OH)_5Cl + 3\ H_2$$

This method is exemplified by the following process [78]:

Aluminum electrodes are set up at distances of 40 mm in a corrosion-resistant electrolysis cell. Hydrochloric acid (ϱ 1.04 g/cm^3) is poured into the cell at a rate such that the reaction temperature remains at ca. 80 °C. After all the hydrochloric acid has been added, the voltage between the first and last electrodes is set so that an average voltage of 0.6 V per electrode pair is obtained at a current density of ca. 170 A/m^2. The formation of explosive gas mixtures must be avoided throughout the reaction by diluting the hydrogen with air or nitrogen to below the explosion limit. After about 70 h, the density of the electrolyte increases to about 1.2 – 1.3 g/cm^3, and the pH value to about 3.5. At the same time the cell voltage falls. The electrolyte then consists of a solution containing aluminum and chloride in the molar ratio 2 : 1, corresponding to a basicity of 83 %. The corresponding bromides as well as iodides are obtained by the same method. The solid halides are obtained from the solutions by careful evaporation or by spray drying [79]. Recently another method may be of interest: Controlled thermic decomposition of $AlCl_3 \times 6\ H_2O$ [86].

Uses and Quality. The most important basic aluminum chloride with regard to consumed quantities are the polyaluminum chlorides (PAC) with basicities in the range of 35 – 60 %. PAC is widely used as a flocculating agent for purifying water. In water treatment PAC can be used for purifying surface water, sewage, and wastewater from industry and municipalities and for water treatment in swimming pools. A second important application for PAC is as fixing sizing agent in the paper industry. Because of the change from acidic to neutral or alkaline sizing, large quantities of aluminum sulfate had to be substituted by PAC. Various qualities are available with aluminum contents between 7.5 and 18.0 %, calculated as aluminum oxide.

Another important basic aluminium chloride has the composition $Al_2(OH)_5Cl \cdot 2 – 3\ H_2O$ and is known in the literature as aluminum chlorohydrate. Very stringent purity specifications apply to this substance. The maximum levels permitted are Fe 100 ppm, SO_4 500 ppm,

Pb 20 ppm, As 3 ppm. These are required for one of its major applications, namely, that in the cosmetics industry as the effective component of antiperspirants [80, 81]; trade names are Chlorhydrol (Reheis, USA) and Locron (Clariant). Other important areas of application for this aluminum chloride are in the production of catalysts and highly temperature-resistant fibers based on Al_2O_3, as a hydrophobic agent for impregnation of cotton textiles, for tanning leather, as a retention agent in paper production, as a binding agent for fire-resistant ceramic products as a hardening agent for rapid fixing baths in the photographic industry and as a flucculant for purifying swimming-pool water.

5. Toxicology

Aluminum sulfate is classified as nontoxic; an LD_{50} value of 6207 mg/kg (mouse, oral) is reported [82]. *Alum* solutions are known for their astringent (tissue-contracting) effects. A TLV of 2 mg/m^3 was established for water-soluble aluminum salts [83].

Anhydrous aluminum chloride has a corrosive and irritant effect on the skin, respiratory tract, and eyes. The toxic effect is caused by the evolution of hydrochloric acid when the product is exposed to moist air. The resulting respiratory difficulties vary from mild irritation to coughing. The MAK value (1995) and TLV (1983) for hydrochloric acid are both 7 mg/m^3 [83, 84].

The extensive use of the *basic aluminum chloride* $Al_2(OH)_5Cl \cdot 2-3\,H_2O$ in the cosmetic industry worldwide over more than 30 years has shown that this compound is not irritating to the skin in the concentrations used commercially. Although intermittent application of 150 mg $Al_2(OH)_5Cl \cdot 2-3\,H_2O$ over a period of 3 days was found to cause mild skin irritation in humans, a dose of only 7.5 mg of $AlCl_3 \cdot 6\,H_2O$ caused the same degree of irritation [85].

1. Introduction

Compounds containing an aluminum – carbon bond are some of the most important, highest volume, highest value organometallic compounds in production. Products ultimately made using these compounds include alcohols, olefins, polyethylene, polypropylene, heat stabilizers, pharmaceuticals, agricultural chemicals, specialty polyolefins, ceramics, and electronic materials. These products are valued in the tens of billions of dollars per year.

Trialkylaluminums and triarylaluminums, R_3Al, alkylaluminum chlorides, R_nAlCl_{3-n} ($n = 1$, 1.5, 2), alkylaluminum hydrides, R_2AlH, and aluminoxanes, $(RAlO)_n$, all have major industrial uses. In addition, various aluminate complexes, $M(I)R_nAlX_{4-n}$, $M(II)[R_nAlX_{4-n}]_2$ – where M represents a metal in group 1 or 2 of the periodic table – have been made.

The organic groups, R, can also possess double or triple bonds or can contain heteroatoms. The R group can bear inorganic nucleophilic substitutents. In addition, various organic groups can bonded to the aluminum atom through oxygen, sulfur, nitrogen, and other atoms (see general references [1–8] for the complete scope of organoaluminum materials).

Organoaluminum chemistry came of age with the studies by Ziegler and asso-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a01_543

ciates, commencing in the early 1950s at the Max Planck Institut für Kohlenforschung, Mülheim/Ruhr, Germany. Of great technical importance was the discovery of the very economic *direct synthesis* of trialkylaluminum compounds, particularly triethylaluminum and triisobutylaluminum, from metallic aluminum, hydrogen, and the olefins ethylene and isobutylene. This process, requiring intermediate formation of aluminum hydride bonds followed by hydroalumination of the olefin, regiospecific in the case of isobutylene, made inexpensive trialkylaluminum materials available.

Other important discoveries within this group included transition-metal coordination catalysts for olefin polymerization; the olefin elimination reaction, which is the reverse of hydroalumination of an olefin; carboalumination of olefins, especially ethylene chain growth; and the controlled air oxidation of aluminum alkyls to alkoxides (for contributions of the ZIEGLER group in organoaluminum chemistry, see [4], [9], [10] → Ziegler Processes).

Other important technical developments, spurred by the availability of economic organoaluminum raw materials, included such diverse applications as alkylation of metal salts, the syntheses of olefin and olefin oligomers, and the use of these compounds as precursors to electronic and ceramic materials.

The report by KAMINSKY and SINN in 1976 that zirconocene – methylaluminoxane (MAO) catalyst systems were highly active in ethylene polymerization has led to a major expansion of research in polyolefin chemistry [11] (→ Metallocenes; → Polyolefins, Chap. 1.3.2.3.). These MAO containing catalyst systems produce a broad slate of conventional polyolefin polymers, sometimes with vastly improved properties, as well as new, exciting polyolefin materials.

2. Alkylaluminums and Derivatives

2.1. Physical Properties

Organoaluminum materials vary in consistency from colorless, mobile liquids through low-melting waxes to crystalline solids. They generally are soluble in aliphatic or aromatic hydrocarbon solvents.

Physical properties of a group of representative alkylaluminum compounds are listed in Table 1. Normal trialkylaluminum compounds exist largely as associated dimers at 25 °C (structure (**1**)). Trialkyls branched on the β carbon, such as triisobutylaluminum, are monomeric. The dialkylaluminum hydrides and amides are trimeric (structure (**2**)). Alkylaluminum chlorides, bromides and iodides are usually dimeric (structure (**3**)). Fluorides are more highly associated. Alkylaluminum alkoxides and mercaptides generally form trimers or higher molecular aggregates.

(**1**) (**2**) (**3**)

Alkyl bridges are considerably weaker than hydride, halide, or other heteroatom bridges. Dimeric trialkylaluminum compounds are in equilibrium with their monomers [12], [13]. The increased dissociation of the dimers with increasing temperature must be considered in reaction rate computations because the monomer generally is the reactive species. The carbon-aluminum bonds in trialkylaluminum compounds are dynamic, rapidly exchanging intermolecularly even under ordinary conditions, and the exchange rate increases with temperature.

2.2. Chemical Properties

The C-Al bonds of organoaluminum materials undergo a wide variety of chemical reactions. For industrial applications, reactions with olefins, metal compounds, carbonyl compounds, oxygen, and proton-donating materials are important in many of the high volume stoichiometric uses of alkylaluminums (see also [1–3], [5–8]). The Lewis acidic properties and reducing characteristics of alkylaluminums are important in high volume catalytic olefin polymerization and oligomerization applications [14]. In addition, alkylaluminums are used to perform a variety of synthetic organic transformations [3–8] and in the clean thermal decomposition to aluminum metal as a basis for metalloorganic chemical vapor deposition (MOCVD) technique

Table 1. Physical properties of alkylaluminum compounds

Compound	M_r	Density, g/mL (°C)	*mp*, °C	*bp*, °C (*p*, kPa)
Trimethylaluminum, $(CH_3)_3Al$ [*75-24-1*]	72.1	0.7478 (25)	15.3	127 (101.3)
Triethylaluminum, $(C_2H_5)_3Al$ [*97-93-8*]	114.2	0.8324 (25)	−46	185 (101.3)
Tri-*n*-propylaluminum, $(n\text{-}C_3H_7)_3Al$ [*102-67-0*]	156.2	0.8207 (25)	<−60	56 (2.7×10^{-2})

Triisobutylaluminum, $(i\text{-}C_4H_9)_3Al$ [*100-99-2*]	198.3	0.7822 (25)	1.0 (1.3×10^{-5})	58–60
Tri-*n*-hexylaluminum $(n\text{-}C_6H_{13})_3Al$ [*1116-73-0*]	282.5	0.8374 (25)	−87	
Tri-*n*-octylaluminum, $(n\text{-}C_8H_{17})_3Al$ [*1070-00-4*]	366.6	0.8336 (25)	<−40	
Diethylaluminum hydride, $(C_2H_5)_2AlH$ [*871-27-2*]	86.1	0.7938 (25)	−59	49–51 (1.3×10^{-4})
Diisobutylaluminum hydride, $(i\text{-}C_4H_9)_2AlH$ [*1191-15-7*]	142.2	0.7989 (25)	−80	89–105 (1.3×10^{-5})
Sodium aluminum diethyl dihydride, $NaAl(C_2H_5)_2H_2$ [*17836-88-3*]	110.1	0.87 * (20)		
Dimethylaluminum chloride, $(CH_3)_2AlCl$ [*1184-58-3*]	92.5	0.9946 (25)	−21	125.7 (101.3)
Diethylaluminum fluoride, $(C_2H_5)_2AlF$ [*367-44-2*]	104.1	0.992 (24)		90–91 (14)
Diethylaluminum chloride, $(C_2H_5)_2AlCl$ [*96-10-6*]	120.6	0.9709 (25)	−74	125 (6.7)
Diethylaluminum bromide, $(C_2H_5)_2AlBr$ [*760-19-0*]	165.0			147–148 (6.7)
Diethylaluminum iodide, $(C_2H_5)_2AlI$ [*2040-00-8*]	212.0	1.5772 (25)	−43	105 (6.7)
Diisobutylaluminum chloride, $(i\text{-}C_4H_9)_2AlCl$ [*1779-25-5*]	176.7	0.9118 (25)	−40	108 (0.13)
Methylaluminum sesquichloride, $(CH_3)_3Al_2Cl_3$ [*12542-85-7*]	205.4	1.1626 (25)	23	143.7 (101.3)
Ethylaluminum sesquichloride, $(C_2H_5)_3Al_2Cl_3$ [*12075-68-2*]	247.5	1.0956 (25)	−21	209.6 (101.3)

in electronic or ceramic applications [15]. The latter are, however, much smaller volume applications.

Alkylaluminums form complexes with nonprotic Lewis base solvents such as ethers or tertiary amines. They react with protic or halogenated solvents such as water, alcohols, ketones, esters, or many chlorocarbons.

2.2.1. Reactions with Olefins

The *hydroalumination reaction* and the reverse process, olefin elimination, are important in economic syntheses of organoaluminum materials [16]:

Table 1. (Continued)

Compound	M_r	Density, g/mL (°C)	*mp*, °C	*bp*, °C (*p*, kPa)
Ethylaluminum sesquibromide, $(C_2H_5)_3Al_2Br_3$ [*12327-99-0*]	380.9			113 (0.53)
Methylaluminum dichloride, CH_3AlCl_2 [*917-65-7*]	112.9		73.6	159 (101.3)
Ethylaluminum dichloride, $C_2H_5AlCl_2$ [*563-43-9*]	127.0	1.227 (35)	31	115 (6.7)
Isobutylaluminum dichloride, *i*-$C_4H_9AlCl_2$ [*1888-87-5*]	155.0	1.1247 (25)	−30	112 (1.3)
Diethylaluminum ethoxide, $(C_2H_5)_2AlOC_2H_5$ [*1586-92-1*]	130.2	0.851 (20)	2	108 – 109 (1.3)
Diethylaluminum thioethoxide, $(C_2H_5)_2AlSC_2H_5$ [*17002-76-5*]	146.2			84 – 85 (6.7×10^{-3})
Diethylaluminum cyanide, $(C_2H_5)_2AlCN$ [*5804-85-3*]	111.1			162 (2.7×10^{-3})
Diethylaluminum dimethylamide, $(C_2H_5)_2AlN(CH_3)_2$ [*13154-82-0*]	129.2			67 – 69 (1.6×10^{-2})

∗ 25 % solution in toluene.

$$R'_2Al-H + CH_2=CHR \rightarrow R'_2AlCH_2CH_2R \quad (1)$$

The rate of addition of the Al – H bond to olefins is greatest for ethylene, and decreases with 1-alkenes, 2-alkyl-1-alkenes, and 1,2-dialkylethylenes. Stability to thermal elimination of the alkene takes the same order.

Triethyl- and higher tri-*n*-alkylaluminum compounds readily add to ethylene [*74-85-1*] or 1-alkenes in a *carboalumination reaction* [17]:

$$R''_2Al(CH_2CH_2R) + CH_2=CHR' \rightarrow R''_2Al(CH_2CHR'CH_2CH_2R) \quad (2)$$

where R, R′ = H or alkyl. When R′ is an alkyl group, the aluminum atom adds to the methylene, as opposed to the methine carbon, in a ratio of ca. 9 : 1. With ethylene, this reaction can repeat, resulting in a *chain growth process.*

$$R''_2Al\,(CH_2CH_3) + n\,CH_2=CH_2 \rightarrow R''_2Al[(CH_2CH_2)_nCH_2CH_3] \quad (3)$$

Starting with triethylaluminum and ethylene, the distribution of alkyl groups in the product follows the Poisson statistical equation. The shape and therefore, the carbon number peak of the curve formed by plotting carbon number vs. weight percentage is a function of the amount of ethylene added. This process results in a primarily linear trialkylaluminum mixture.

Alkylaluminum compounds with branches in the β position add to another olefin molecule only with difficulty. But, these branched compounds readily eliminates a branched 2-alkyl-1-alkene, generally called a *vinylidene olefin:*

$$R''_2Al(CH_2CHR'CH_2CH_2R) \rightarrow CH_2=CR'CH_2CH_2R + R''_2AlH \quad (4)$$

where R = H or alkyl; R′ = alkyl

2.2.2. Reactions with Oxygen

The carbon-aluminum bonds in organoaluminum compounds react readily with oxygen [*7782-44-7*] by an exothermic radical chain mechanism that, under controlled conditions, can give high yields of aluminum alkoxide but low yields of aryloxide with alkyl and aryl groups, respectively [1–4], [18]. With a trialkylaluminum material, the overall reaction is:

$$2\,R_3Al + 3\,O_2 \rightarrow 2\,Al(OR)_3 \quad (5)$$

The molar heat of reaction ($\Delta H = -1071$ kJ/mol at 25 °C [19]) is sufficiently great that, exposure of concentrated organoaluminum materials to air can produce an uncontrolled reaction with oxygen. The heat is so concentrated that the kindling temperature of the material is exceeded and spontaneous flaming occurs.

Establishing conditions for effective control of the oxidation reaction was an important contribution in development of the large volume industrial process for linear primary alcohols utilizing organoaluminum chemistry.

2.2.3. Reactions with Metal Compounds

Several types of reactions of organoaluminum compounds with metal salts can be distinguished.

Salts of more electronegative main-group metals or metalloids, particularly those in groups 12 through 15, frequently undergo *alkylation* by organoaluminum materials [20]. An example, with a group 12 metal salt, is the reaction of triethylaluminum with zinc chloride [*7646-85-7*] to form diethylzinc [*557-20-0*], which can be separated by distillation from coproduct diethylaluminum chloride.

$$2\,Al(C_2H_5)_3 + ZnCl_2 \rightarrow Zn(C_2H_5)_2 + Al(C_2H_5)_2Cl \quad (6)$$

Another industrially important example is the production of tin(IV) alkyls from stannic chloride [*7646-78-8*] [21]:

$$4\,R_3Al + 3\,SnCl_4 \rightarrow 3\,SnR_4 + 4\,AlCl_3 \quad (7)$$

$R = n\text{-}C_6H_{13}$ or $n\text{-}C_8H_{17}$

Saltlike complexes are formed with the more electropositive elements, especially group 1 and 2 metals [22]. For example, when triethylaluminum is heated with sodium fluoride [*7681-49-4*] at 100 – 120 °C, a stable complex results.

$$(C_2H_5)_3Al + NaF \rightarrow Na[Al(C_2H_5)_3F] \quad (8)$$

Complex formation is also possible with quaternary ammonium, phosphonium, or sulfonium type salts. These complexes are used as ionic liquids. Liquid clathrate formation is an interesting property of these saltlike complexes and has potential applications in coal liquefaction [23].

Reductions often occur when alkylaluminum compounds are allowed to react with transition-metal compounds. Depending on reactants, stoichiometry, and conditions, either completely reduced, finely divided, very active metals result, or reduced coordination complexes are formed [10], [14]. The latter, which include Ziegler – Natta and other coordination catalysts, show remarkable catalytic effects in oligomerizations, polymerizations, and other reactions of olefinic materials.

2.2.4. Reactions with Proton-Donating Materials

Most protonolysis reactions of alkylaluminum compounds are very exothermic, but under controlled conditions they can be used to prepare such materials as alkylaluminum alkoxides [24], [25], cyanides [26], [27] mercaptides [25], [28], halides, or dialkylamides [25]:

$$R_3Al + HZ \rightarrow R_2AlZ + RH \quad (9)$$

The active hydrogen reagent (HZ) may be mineral acid, water, an alcohol or a mercaptan, a phenol, carboxylic acid, ammonia or amine, or even mono- or unsubstituted acetylene.

When conditions are not controlled, thermal degradation also can take place, forming a mixture containing olefins and hydrogen as well as the alkane in the case of alkylaluminum materials. With water or other reagents that form aluminum-oxygen bonds, the reaction is highly exothermic. If water is added to an organoaluminum compound that is burning in air, therefore, a very violent reaction can ensue.

Protonolysis is also an important technique for preparing organoaluminum compounds for analysis.

2.2.5. Alkylaluminums in Organic Synthesis

The reactions of alkylaluminum reagents with organic functional groups has been the subject of much research [1–8]. Two further reactions of alklyaluminums have reasonable industrial significance.

First, numerous examples have been reported of *alkylation of the carbonyl carbon* in acyl halides, ketones, acid anhydrides, ketenes, esters, lactones, and aldehydes using alkylaluminum compounds. Alcohols are formed after hydrolysis [3], [4], [5].

(10)

Diisobutylaluminum hydride or other complex organoaluminum hydrides are useful reagents for reduction of the aldehyde or ketone carbonyl function to an alcohol [1–5], [7], [8].

(11)

Second, *alkynes* can be stereoselectively hydroaluminated. After hydrolysis, the products formed are exclusively cis-alkenes [6].

(12)

2.3. Production of Trialkylaluminums and Alkylaluminum Chlorides

Trialkylaluminums are available industrially via the reactions of aluminum [*7429-90-5*] with hydrogen plus alkenes, or by reduction of alkylaluminum halides. *Alkylaluminum halides* are produced by reaction of hydrogen halides with trialkylaluminums, or by direct reaction of aluminum with an alkyl halide. *Alkylaluminum hydrides* and other products are produced by several conversion methods.

Often the method of synthesis has a great influence on the quality of an organoaluminum material in terms of the presence of trace components. In addition, the hydroalumination method is inherently safer to practice industrially than the reaction of aluminum metal with an alkyl chloride followed by reduction.

2.3.1. Hydroalumination to Produce Trialkylaluminums

Under the activating influence of an alkylaluminum compound, again in the absence of air or moisture, finely divided aluminum metal reacts directly with hydrogen [*1333-74-0*] to form an Al – H bond. A 1-alkene or 2-alkyl-1-alkene can then add by hydroalumination to give the primary trialkylaluminum product [16].

With ethylene and *n*-1-alkenes, a two-step approach can be used.

$$4\,R_3Al + 2\,Al + 3\,H_2 \rightarrow 6\,R_2AlH \qquad (13)$$

$$R = C_2H_5,\ i\text{-}C_4H_9,\ n\text{-}C_4H_9,\ n\text{-}C_6H_{13},\ n\text{-}C_8H_{17},$$
$$110 - 140\,^\circ C,\ 5 - 20\,MPa$$

$$6\,R_2AlH + 6\,(1\text{-alkene}) \rightarrow 6\,R_3Al$$
$$80 - 100\,^\circ C \qquad (14)$$

In the first step, Equation 13, the Al – H bond is formed and stabilized as the dialkylaluminum hydride. A relatively high temperature is required to achieve an acceptable reaction rate. Air-blown aluminum powder is suitable for the process. Formation of Al – H bonds can be accelerated by milling the aluminum powder in the presence of the trialkylaluminum product [29], or by alloying certain transition metals, such as titanium or zirconium, with the aluminum powder [30]. Among other catalysts reported for the reaction are sodium alcoholates [31], sodium metal [32], and sodium hydride [32].

In the second step, Equation 14, the olefin adds rapidly at a decreased temperature where unwanted carboalumination of the olefin is negligible.

Triethylaluminum (TEA), tri-*n*-butylaluminum (TNBA), triisobutylaluminum (TIBA), tri-*n*-hexylaluminum (TNHA), and tri-*n*-octylaluminum (TNOA) can be produced by the two-step approach, which has been referred to as the three-for-two process. Both steps can also be carried out simultaneously: in this case, the feed ratio of hydrogen to olefin must be controlled carefully [33–37]. Both batch and continuous triethylaluminum processes have been described in patents [33–35].

Straight-chain alkylaluminums made by the hydroalumination process generally contains some residual Al – H groups. They also contain higher-chain groups that form through the competing ethylene chain – growth reaction. When higher trialkylaluminum products are made from 1-alkenes, the process-related impurities include, along with Al – H bonds, some β-branched alkyl groups, which can be referred to as 1-alkene dimer groups. Triisobutylaluminum contains no long-chain impurities because isobutene [*115-11-7*] does not undergo chain growth.

The synthesis of lower hydride straight-chain alkyls is accomplished by increasing the 1-alkene concentration during production. The materials, however, contain higher levels of longer-chain alkyl byproducts.

Crude triethylaluminum can be purified by fractional distillation. Distillation of the higher trialkylaluminum products is difficult because of their relatively low vapor pressures. Furthermore, temperatures required for distillation of TNBA, TIBA, TNHA, and TNOA are usually high enough to result in thermal elimination of 1-alkene and the concomitant introduction of Al – H groups. These more thermally sensitive alkyls are purified by either by filtration or by wiped film evaporation.

Figure 1. Continuous two-step process for triethylaluminum
a) Hydriding reactor; b) Flash drum; c) Ethylation reactor; d) Flash drum.

Process Example. A flow scheme for a continuous two-step industrial production of triethylaluminum is represented in Figure 1 [36]. The hydriding reactor (a) is of the vertical cylinder type, 3.8 m^3 in volume. In a typical example, a slurry is prepared containing 7 wt % aluminum powder (0.1 wt % zirconium catalyst content) and 45 wt % recycled triethylaluminum in a paraffin hydrocarbon fraction, boiling range 177 – 260 °C. The slurry is pumped into the reactor at a rate of 1.5 m^3/h, at a reactor temperature of 132 °C, while hydrogen is introduced at the bottom to maintain a partial pressure of 10 MPa. Diethylaluminum hydride is formed according to Equation 4, and is present at a concentration of 83 wt % in the stream flowing from the reactor.

Excess hydrogen is removed in flash drum (b), wherein pressure is decreased to 3 MPa and temperature is lowered to prevent thermal reversal of the reaction.

In the ethylation reactor (c) sufficient ethylene is added to react completely with the Al – H bonds (Eq. 5). Temperature is held at around 85 °C or somewhat higher. The addition rate increases with temperature, but carboalumination of ethylene also can occur to form *n*-butyl groups, especially at higher temperatures. Hydrogen and ethylene partial pressure is kept low in (c) to minimize hydrogenation of ethylene to ethane and to reduce excess carboalumination products.

Excess ethylene and hydrogen are removed in flash drum (d). A portion of the triethylaluminum product solution is recycled to reactor (a). The remainder may be used as such, or, if the solvent is a hydrocarbon of higher boiling range, pure triethylaluminum may be separated from it by distillation.

2.3.2. Reaction of Aluminum With Alkyl Halides to Make Alkylaluminum Sesquichlorides

Methyl, ethyl, and other alkyl or aralkyl halides that are not dehydrohalogenated readily, can react with aluminum metal in an exothermic process to form organoaluminum sesquihalides in high yields [38], [39]. An important example is the reaction of methyl chloride [*74-87-3*] with aluminum [*7429-90-5*].

$$3\,CH_3Cl + 2\,Al \rightarrow (CH_3)_3Al_2Cl_3 \qquad (15)$$

The reaction is carried out with aluminum in the form of turnings, shavings, granules, or powder. Oxygen and moisture must be rigorously

excluded. The reaction can be initiated with a small amount of mercury or iodine. It also can be started by treating the aluminum with an alkylaluminum halide. A portion of the residue from a previous reaction is effective.

The products are equilibrium mixtures of the codimer ($R_2AlX \cdot RAlX_2$) and homodimers [$(R_2AlX)_2$ and $(RAlX_2)_2$], in which the two aluminum atoms of each component are halogen-bridged as shown by compound (**3**), Section 2.1.

In the reaction of methyl chloride [*74-87-3*] with aluminum, small amounts of ethane are formed by an apparent Wurtz-like reaction. With ethyl chloride, some butane is produced; also, dehydrochlorination of ethyl chloride can occur to form byproduct ethylene and excess Al – Cl bonds in the product. The ethylene may form oligomers in the mixture by a cationic mechanism. The byproduct reactions are favored by higher temperatures and therefore can be minimized by careful temperature control. When byproduct reactions take place to a significant extent, the excess Al – Cl content in the $R_3Al_2Cl_3$ product can be decreased by addition of the calculated amount of R_3Al. Overall, however, it is critical to control reaction conditions as slight excursions can result in catastrophic events.

Products can be recovered by settling and decantation, filtration, or distillation. Large quantities of methyl- and ethylaluminum sesquichlorides are produced industrially by this method. They are used as alkylating agents, catalyst components, and for making other methyl- or ethylaluminum chlorides.

Process Example. Production of ethylaluminum sesquichloride by reaction of ethyl chloride with aluminum is illustrated by this patent example [39]. A $9.5 \times 10^{-2}\,m^3$ closed steel reactor, fitted with a reflux condenser and equipped for vacuum distillation of product, was first purged with nitrogen. After addition of 13.6 kg of aluminum powder and a catalyst mixture composed of 3.6 kg diethylaluminum chloride and 410 g iodine [*7553-56-2*], the reactor contents were stirred and heated slowly to 130 °C. The temperature was maintained at 120 – 150 °C during addition of 50 kg ethyl chloride over a period of 3 h.

The product can be flash distilled under vacuum, or it can be drained from the reactor and clarified by settling or by filtration of black residual metal solids. Iodine can be omitted from the procedure, in which case the induction period may be increased.

2.3.3. Reduction of Alkylaluminum Sesquichlorides to Make Trialkylaluminums

The alkylaluminum sesquihalide products from aluminum reactions with alkyl halides can be converted to dialkylaluminum halide or trialkylaluminum materials by treatment with *active metals*, such as sodium [*7440-23-5*] or magnesium [*7439-95-4*] [38], [39]. For example, diethylaluminum chloride or triethylaluminum can be produced from ethylaluminum sesquichloride by sodium reduction.

$$2\,(C_2H_5)_3Al_2Cl_3 + 3\,Na \rightarrow 3\,(C_2H_5)_2AlCl + Al + 3\,NaCl \quad (16)$$

$$3\,(C_2H_5)_2AlCl + 3\,Na \rightarrow 2\,(C_2H_5)_3Al + Al + 3\,NaCl \quad (17)$$

A magnesium-aluminum alloy can provide the reduction function concurrently with reaction between aluminum and the alkyl halide.

$$4\,C_2H_5Cl + Al_2Mg \rightarrow 2\,(C_2H_5)_2AlCl + MgCl_2 \quad (18)$$

The sesquichloride reduction process is currently the most economical route available for production of trimethylaluminum.

Trialkylaluminum products made by this process generally contain trace levels of residual chloride but do not contain Al – H or other low-level components found in the aluminum-hydrogen-olefin processes (Section 2.3.1).

The components of ethylaluminum sesquichloride cannot be separated economically by fractional distillation because of unfavorable vapor pressure relationships. However, diethylaluminum chloride can be distilled from the crystalline sodium chloride complex that forms with ethylaluminum dichloride [22].

$$(C_2H_5)_3Al_2Cl_3 + NaCl \rightarrow (C_2H_5)_2AlCl + Na[Al(C_2H_5)Cl_3] \quad (19)$$

Process Example. Diethylaluminum chloride has been made industrially according to Equation 16. In a patent example [39], ethylaluminum sesquichloride (26.5 kg) added to a nitrogen-purged $9.5 \times 10^{-2}\,m^3$ reactor, was heated to 175 °C. Then, while the mixture was stirred vigorously, 1.1 kg sodium was added over a 30 min period; the mixture was further heated at 155 – 190 °C for 60 min. The diethylaluminum chloride product distilled from the reactor at 100 – 161 °C (1.3 – 6.1 kPa).

In this example, an excess of ethylaluminum sesquichloride was employed to facilitate draining the voluminous byproduct salt and aluminum solids from the reactor. In an alternate approach, a heavy hydrocarbon oil, added prior to reaction, may be employed to remove the solids in slurry form, permitting the use of a stoichiometric ratio of ethylaluminum sesquichloride and sodium reactants.

2.3.4. Reaction of Acids With Trialkylaluminums to Produce Alkylaluminum Chlorides

Diethylaluminum chloride (DEAC), ethylaluminum sesquichloride (EASC), and ethylaluminum dichloride (EADC) can all be prepared by the reaction of triethylaluminum with HCl:

$$(C_2H_5)_3Al + n\,HCl \rightarrow (C_2H_5)_{(3-n)}AlCl_n + n\,C_2H_6 \qquad n = 1, 1.5, 2 \quad (20)$$

The products or their derivatives are used as components of catalysts for the production of polyolefins and some elastomers.

2.3.5. Reproportionation Reactions

When alkylaluminum halide or trialkylaluminum compounds and aluminum trihalides are combined, reproportionation reactions occur rapidly under ambient blending conditions, releasing small amounts of energy [38], [39]. These reactions are of industrial importance in making, e.g., diethylaluminum chloride or ethylaluminum dichloride. Either can be formed, depending upon reactants and stoichiometry chosen.

$$2\,(C_2H_5)_3Al + AlCl_3 \rightarrow 3\,(C_2H_5)_2AlCl \quad (21)$$

$$(C_2H_5)_3Al + 2\,AlCl_3 \rightarrow 3\,C_2H_5AlCl_2 \quad (22)$$

$$(C_2H_5)_3Al_2Cl_3 + (C_2H_5)_3Al \rightarrow 3\,(C_2H_5)_2AlCl \quad (23)$$

$$(C_2H_5)_2AlCl + AlCl_3 \rightarrow 2\,(C_2H_5)AlCl_2 \quad (24)$$

This method is particularly useful for making alkylaluminum halides that cannot be produced via the reactions of aluminum with alkyl halide, e.g., diisobutylaluminum chloride and isobutylaluminum dichloride. These are preferred over the corresponding ethyl homologues as co-catalysts in certain olefin polymerization systems.

2.3.6. Olefin Elimination and Displacement Reactions

2-Alkyl-1-alkene olefins are readily eliminated from β-branched trialkylaluminum compounds. In the most common of these compounds, TIBA, a substantial level of Al – H bonds are present at equilibrium. Diisobutylaluminum hydride (DIBAH) is commercially produced by slow thermolysis of TIBA with concurrent removal of the formed isobutene:

$$(i\text{-}C_4H_9)_3Al \rightarrow (i\text{-}C_4H_9)_2AlH + i\text{-}C_4H_8 \quad (25)$$

The greater stability of unbranched trialkylaluminum compounds relative to branched trialkylaluminum compounds in TIBA or DIBAH forms the basis for a general synthesis of triethyl- and higher linear trialkylaluminum materials from triisobutylaluminum or diisobutylaluminum hydride [40].

$$(i\text{-}C_4H_9)_3Al + 3\,RCH{=}CH_2 \rightarrow (RCH_2CH_2)_3Al + 3\,i\text{-}C_4H_8 \quad (26)$$

When the displacing olefin is a 1-alkene, the competing carboalumination reaction of 1-alkene with product trialkylaluminum can be minimized by careful temperature control and, particularly in a batch system, by maintaining a relatively high Al – H concentration. The latter condition is achieved by continuous removal of isobutene from the system while the displacing 1-alkene is fed at a limited rate.

The triisobutylaluminum displacement process can be used for production of triethylaluminum, owing to greater stability of ethylaluminum over isobutylaluminum groups. The resulting triethylaluminum product contains some residual isobutyl groups, in addition to the Al – H and chain – growth alkyl groups inherent in the ethylene hydroalumination process. When using 1-alkenes in the displacement process, small amounts of dimer alkyl groups are formed by carboalumination.

Triethyl-, tri-*n*-propyl-, or tri-*n*-butylaluminum products made by the displacement process can be purified by distillation. Displacement products of the higher alkylaluminums of good quality can be obtained by beginning with triisobutylaluminum or diisobutylaluminum hydride of good purity, carrying out the reaction with a slight excess of 1-alkene, and then carefully removing excess 1-alkene at a minimum temperature under vacuum.

Several trialkylaluminum products, e.g., TEA, TNHA, and TNOA, are made industrially by this process. A product mixture, referred to as "isoprenylaluminum", is produced by partial displacement of isobutene from triisobutylaluminum by isoprene [41], [42].

2.3.7. Other Organoaluminum Conversions

Preparation of a typical *organoaluminum fluoride,* diethylaluminum fluoride, has been reported via the reaction of diethylaluminum chloride with sodium fluoride [43].

$$(C_2H_5)_2AlCl + NaF \rightarrow (C_2H_5)_2AlF + NaCl \quad (27)$$

Diethylaluminum iodide can be prepared by concurrent reaction of iodine [*7553-56-2*] and aluminum with triethylaluminum [44], [45], [46].

$$4\,(C_2H_5)_3Al + 3\,I_2 + 2\,Al \rightarrow 6\,(C_2H_5)_2AlI \quad (28)$$

2.4. Uses of Alkylaluminum Compounds

Industrial uses for organoaluminum materials include a number of stoichiometric and catalytic applications that consume hundreds of thousands of tonnes each year.

2.4.1. Stoichiometric Applications

Undoubtedly the stoichiometric use that consumes the most alkylaluminum material is the production of linear primary alcohols (→ Alcohols, Aliphatic, → Ziegler Processes). Triethylaluminum is the single most important organoaluminum material on a volume basis.

A long-chain trialkylaluminum intermediate is first made by chain growth of ethylene on TEA or by the displacement of the alkyl group by a higher-chain α-olefin. The long-chain alkylaluminum compound is oxidized with oxygen, and the resulting aluminum trialkoxide is hydrolyzed to produce the primary alcohol.

The products are even carbon number, primary alcohols, that are large-volume intermediates to poly(vinyl chloride) plasticizer esters ($C_6 - C_{10}$) and numerous surfactant derivatives ($C_{10} - C_{18}$).

The second largest volume use of alkylaluminums is to make linear α-olefins. These are produced first by chain growth of ethylene on triethylaluminum to produce a long-chain alkylaluminum compound. This long-chain alkylaluminum compound is reacted with another olefin such as ethylene which displaces the long-chain alkyl as the α-olefin and regenerates the triethylaluminum. Product olefins are separated from the TEA, which is recycled.

Linear α-olefins are highly versatile intermediates to a number of important products [46]. The main uses are in the production of copolymers, surfactants, and lubricants. Linear low density polyethylene is a copolymer of ethylene with either C_4, C_6, or C_8; C_{18} is used as a comonomer with either maleic anhydride [*108-31-6*] or 1-vinyl-2-pyrrolidinone [*88-12-0*]. Surfactants are made from C_8, C_{10}, and C_{12} alcohols as such or from the derivatized alcohol sulfonates, ethoxylates, sulfonated ethoxylates, and alkylated phenols. Poly-α-olefins, the major basestock in synthetic hydrocarbon lubricants, are based on C_{10} oligomers; derivatives of C_{20} and higher fractions are used as oil pour-point depressants, engine oil detergents, and other engine oil additives or as paper sizing agents. In addition, C_{20} and higher fractions are used as waxes and in investment casting.

Another stoichiometric application of alkylaluminum compounds is in the alkylation of metals or metalloid salts to produce organometallic products. These products include derivatives of zinc, boron, silicon, lead, mercury, tin, and phosphorus. The largest volume of materials produced this way are tetraalkyltin(IV) compounds. These compounds are derivatized to alkyltin carboxylates or to alkyltin mercaptides which are used in such applications as poly(vinyl chloride) heat stabilizers, microbiocides, and catalysts [47].

Uses of organoaluminum materials in organic syntheses, particularly in the production of specialty chemical products, e.g., pharmaceuticals, fragrances, and certain pesticides, have received much attention [3–6]. Alkylaluminums, particularly high purity trimethylaluminum, are also used as precursors to high purity alumina and aluminum containing electronic materials and ceramics.

2.4.2. Catalytic Applications

The longest known industrial use of organoaluminum materials is in Ziegler – Natta catalysts for olefin and diene polymerizations [14]. In this use alkylaluminums reduce a transition metal compound, typically of titanium or vanadium, to a catalytically active oxidation state. They then alkylate the catalyst to form the metal – alkyl bond that is the site of monomer insertion and polymerization. They also serve as poison scavengers within the polymerization reactor. Additionally, they can become a part of the active coordination catalyst complex.

Industrially important polymers that utilize Ziegler – Natta or other coordination catalysts in their production include high-density polyethylene, isotactic polypropene, both plastic and elastomeric ethylene-propylene copolymers, ethylen – propene – diene (EPDM) terpolymers, isotactic poly-1-butene, cis-polydiene elastomers, high-density polyethylene, and the linear low- and medium-density polyethylenes that contain low levels of butene, hexene or octene comonomers.

Important products from reactions using other coordination catalysts are, for example, cyclic dimers or trimers from butadiene and linear α-olefin oligomers from ethylene; C_6 and C_8 materials from propene and linear butene dimerization, used in gasoline blending and C_9 oxoalcohol production, respectively; and synthetic lubricants, hydraulic fluids, and waxes from oligomerizing ethylene and 1-alkenes. The catalysts also are used for the ring-opening polymerization of cyclic olefins, e.g., in conversion of cyclopentene to polypentenamer elastomer, or the olefin redistribution reaction, as in the conversion of propene to its equilibrium mixture with ethylene and 2-butene.

Effective homogeneous hydrogenation catalysts can be made by reduction of transition-metal salts with alkylaluminum compounds.

2.5. Quality Specifications

For some applications of alkylaluminum materials, e.g., for syntheses of olefins from trialkylaluminum compounds, the major quality criterion is simply total R_3Al content. The processes are not affected significantly by trace impurities. For other applications, however, such as in the use of R_3Al or R_2AlX in preparing certain coordination catalysts for olefin polymerizations, even low levels of hydride or alkoxide can affect catalyst activity. In addition, keeping the halogen : aluminum atomic ratio within a narrow set of limits can be important.

When diethylaluminum chloride is used as an activator for some Ti(III)-based polypropylene catalysts, the presence of hydrogen as hydride at levels in excess of 0.05 mol % of the ethyl groups may decrease stereoselectivity. The presence of oxygen as ethoxide at O : Al atomic ratios below 0.1 may increase activity for some systems, whereas above 0.1 the activity usually is decreased.

The Cl : Al atom ratio must be controlled between 0.97 and 1.03, either near the lower limit or the higher limit, depending on other catalyst components and on various process factors.

During the analysis of organoaluminum materials, extreme care must be taken, because exposure to traces of air can lead to oxidation or hydrolysis. Also, thermal degradation may result during the hydrolysis that precedes gas chromatography [24].

Halogen and *total aluminum* content in organoaluminum materials are determined by advanced methods on hydrolysis solutions that

are based on state-of-the-art titration equipment and computerized data enhancement. Standard deviations of the advanced methods are significantly lower than conventional methods. *Active aluminum,* i.e., the aluminum in trialkylaluminum and dialkylaluminum hydride form, can be determined by careful protonolysis with ammonia or amines [48], [49].

Dialkylaluminum hydrides have been, in the past, assayed by spectrophotometric measurement of complexes with an azomethine compound, such as isoquinoline [49]. The isoquinoline analysis has been replaced with more accurate and precise analytical methods based on gas chromatography and NMR. Hydrolysis of organoaluminum compounds followed by capillary gas chromatography of the gaseous phase using a megabore molecular sieve column is effective for determining hydride and alkyl content of organoaluminum compounds. The liquid organic hydrolysis products are determined by standard capillary gas chromatography techniques. Another approach to measurement of hydride and alkyl group content in organoaluminum materials is ^{1}H-NMR spectroscopy. The ^{1}H-NMR analysis avoids the lengthy and labor intensive gas evolution analyses and directly measures the hydride and alkyl groups. No calibration is needed. Further, the limit of detection is very low and the precision is high. In a single NMR analysis the hydride, identity of alkoxide impurities, and alkyl group content can be determined. Best results are obtained using a 300 MHz or higher field NMR instrument [50].

Oxygen at trace levels in the form Al – O – Al is generally not measured directly in organoaluminum materials. Alkoxide oxygen is determined readily, however, even at low concentrations directly by NMR.

3. Aluminoxanes

3.1. Production

Aluminoxanes are produced by the partial hydrolysis of alkylaluminum compounds with water [5], [51]:

$$n\,R_3Al + n\,H_2O \longrightarrow \left(\begin{array}{c} R \\ | \\ Al-O \end{array}\right)_n + 2n\ RH \qquad (29)$$

Methylaluminoxane (MAO) [*120144-90-3*], is by far the industrially most significant aluminoxane. The direct hydrolysis of trimethylaluminum (TMA) with water, however, is extremely exothermic and difficult to control. Thus, small scale, continuous processes, rather than large scale batch processes, are used for the direct hydrolysis of TMA to MAO [52].

MAO can also be produced by reaction of TMA with organic acids, ketones, or carbon dioxide [51], [53]. The synthesis of MAO from TMA and CO_2 actually has substantial literature precedent [5], [51], [54]. Carbonation of an organoaluminum compound with carbon dioxide forms an aluminum carboxylate:

$$R_3Al + CO_2 \rightarrow R_2Al\text{-}OCOR \qquad (30)$$

With an excess of carbon dioxide, a trialkylaluminum compound gives $R_2AlOCOR$ in good yield, but conversion of the second alkyl group to carboxylate proceeds with difficulty. Conditions have not been found for reaction of the third group. Reaction of excess trialkylaluminum with carbon dioxide produces what was originally reported as a low molecular mass alkylaluminoxane dimer and aluminum carboxylate.

$$R_2AlOCOR + 2\,R_3Al \rightarrow (R_2Al)_2O + R_2AlOCR_3 \qquad (31)$$

Isobutylaluminoxane. In contrast, the direct hydrolysis of triisobutylaluminum (TIBA) to produce isobutylaluminoxane (IBAO) proceeds less violently and can be performed in large batch scale operations [55], [56].

Mixed alkylaluminoxanes are aluminoxanes that typically contain 60 to 85 mol % methyl groups while the remaining alkyl groups are of a higher carbon number. A methyl – isobutyl mixed alkyl aluminoxane can be produced by diluting IBAO with TMA and then hydrolyzing the excess alkyl groups [55], [56]. Mixed alkyl aluminoxanes containing other alkyl groups can also be produced by hydrolyzing mixtures of TMA with another alkylaluminum [57].

3.2. Physical and Chemical Properties

Solvent free MAO is a glassy solid at room temperature. Other aluminoxanes such as IBAO and mixed alkylaluminoxanes are viscous oils at room temperature. Most aluminoxanes, however, are used as solutions in hydrocarbons. IBAO and mixed alkylaluminoxanes are available in toluene or saturated hydrocarbon solutions. Unmodified MAO is sold only in toluene because it is only sparingly soluble in saturated hydrocarbons.

Solid state molecular structures have been determined for many different *tert*-butylaluminoxane oligomers; two representatives are shown below [58]:

The structure of most aluminoxanes, however, is not well defined. Aluminoxanes are mixtures of oligomers of $n = 2$ to 20. Many structures have been proposed for aluminoxanes including rings, cages, and linear molecules [51]. It is likely that multiple equilibria exist in solution which interconvert the oligomer sizes and structures, particularly for MAO.

All commercially available MAO products contain residual TMA associated with the MAO. The level of TMA varies among manufacturers [59].

Although MAO can be produced as a clear, colorless solution in toluene, undisturbed solutions will precipitate hard gels over time as shown in Figure 2. Eventually, a 30 wt % solution of MAO will form a single gelatinous mass. Although the mass can be shaken or stirred to permit the material bulk to flow, the MAO solution will remain opaque with the presence of small, hard gels that cannot be redissolved into hydrocarbon solution. Figure 3 shows that refrigeration of MAO can significantly retard gel formation. IBAO and mixed alkyl aluminoxanes are much more stable and less likely to form gels than MAO.

Figure 2. Formation of gels in MAO – toluene solutions over time at 25 °C

Figure 3. Formation of gels in 30 wt % MAO in toluene solutions at different temperatures

Like other organoaluminum compounds, aluminoxanes are extremely reactive toward oxygen and water and toward oxygenated and halogenated compounds.

3.3. Uses

Aluminoxanes are used industrially exclusively as cocatalysts in the polymerization of olefins (→ Metallocenes; → Polyolefins, Chap. 1.3.2.3.). Cyclopentadiene derivatives of zirconium, titanium, and hafnium are the primary catalysts used industrially [60]. But organometallic compounds based on nickel are also industrially important [61], and catalysts based on cobalt and iron have been identified [62].

Activities of 1 to 10 t of polyethylene per mole of transition metal are observed in these catalyst systems. Different molar alu-

minum : transition metal atomic ratios of one thousand to several hundred to one hundred or even less are used, depending on the catalyst system. A multitude of zirconocene and hafnocene derivatives, when used with MAO, are all active for the polymerization of olefins. No obvious correlation between catalyst activity and catalyst structure, however, has been shown [60].

3.3.1. Mechanism of Polymerization Using Aluminoxanes (→ Metallocenes; → Polyolefins, Chap. 1.3.2.3.)

The role of MAO in metallocene catalyst polymerization is fourfold. First, it alkylates the transition metal. Second, it extracts an alkyl group from the transition metal to generate an active cationic polymerization catalyst. Third, it acts as a bulky, inert anion to the highly reactive transition metal cation. Fourth, it scavenges impurities from the polymerization reactor [5].

Figure 4. Mechanism of olefin polymerization using zirconocene with MAO catalysts

The mechanism of olefin polymerization using zirconocene/MAO catalysts has been well studied [63–67]. A representative mechanism is shown in Figure 4. When using bis(cyclopentadienyl) derivatives of zirconocene dichloride as the catalyst precursor, MAO first alkylates the zirconocene center to form a zirconocene dimethyl complex. The MAO further reacts with the zirconocene dimethyl compound, formally extracting a methyl anion, to produce a 14-valence-electron zirconocene monomethyl cation that has a vacant coordination site and a metal – alkyl bond.

The incoming olefin first coordinates to the vacant site on the metal, after which the alkyl group bound to the zirconocene center migrates to the β position on the olefin. This regenerates a zirconocene monoalkyl cation, which continues to insert olefins into the growing polymer chain. By this mechanism, the active polymerization site moves back and forth from one side of the molecule to the other.

The polymer chain is terminated by β-hydride elimination leaving the active catalyst site, a transition metal monohydride cation, which can begin the polymerization process anew.

After generating the active zirconocene methyl cation, the altered MAO acts as a surprisingly inert anion to the polymerization. Most common "inert" anions such as BF_4^-, BPh_4^-, and PF_6^- poison the zirconocene monoalkyl cation catalyst. Unique fluorinated borates such as $B(C_6F_5)_4^-$ [68], [69] and $MeB(C_6F_5)_3^-$ [64], [70] also do not react with the active catalyst and can be used industrially in these systems. Since the metallocene/borane systems are well defined molecular compounds, they have permitted the study and elucidation of the polymerization mechanism of this system to a degree never before seen with other catalysts.

On an industrial scale, MAO also acts as a scavenger of low level catalyst poisons such as oxygen, water, amines, sulfides, etc. The borane systems do not have the same poison scavenging ability that aluminoxanes do, and thus require much more strenuously clean reactor conditions.

3.3.2. Production of Stereoregular Polymers using Aluminoxanes

The so-called "windshield wiper" mechanism described in Figure 4 facilitates the production of stereoregular polymers, as shown in Figure 5. For example, consider the family of linked bis-indenyl zirconocene *ansa*-metallocene complexes shown below:

Figure 5. Synthesis of stereoregular polymers using *ansa*-metallocenes with MAO. (The bridged bis-indenyl ligand is depicted by two heavy lines for clarity.) The resting state of the catalyst is a zirconocene alkyl cation. Steric interactions direct the growing polymer chain to the open area away from the bulky indenyl ligand. This stereochemistry is further locked into place by an agostic interaction between an α-hydrogen on the polymer chain and the zirconium atom. Propene inserts, forming a metallocycle intermediate, with the propene methyl group trans to the polymer chain to minimize steric interaction. Migratory addition of the polymer chain switches the positions of the open coordination site and the growing polymer chain. Again, the intermediate is stabilized by an α-agostic interaction, and the polymer chain is directed away from the bulky indene ligand. Another propene coordinates to the vacant coordination site, the process repeats, and isotactic polypropylene is formed.

rac-isomers

meso-isomer

The salient structural feature of these metallocene compounds, first studied by Brintzinger et. al., is that the two cyclopentadiene rings are linked together by a bridging group, which locks the relative stereochemistry of the two rings in place [71]. The *ansa*-zirconocene system exists as three different isomers: a racemic pair of enantiomers, called *rac*-, and a *meso*- diastereomer. When used with MAO cocatalyst, the *rac*- isomers polymerize α-olefins; the incoming monomer inserts into the growing polymer chain such that the pendant alkyl groups all wind up on the same side of the polymer molecule, producing isotactic stereochemistry. The *meso*- isomer produces atactic polypropylene under the same conditions.

In contrast, the cyclopentadiene – fluorenyl linked derivative shown below forces the pendant alkyl groups to alternate from one side of the polymer molecule to the other, creating syndiotactic polymer [63].

In all these cases, the minimization of steric interaction between the polymer, ligands, and incoming monomer drives the ultimate configuration of the polymer. An α-agostic interaction of the polymer with the transition metal center also helps control polymer stereochemistry [72].

3.3.3. Polymers Produced by Aluminoxanes

High molecular mass polyolefins are commonly produced industrially using either chromium on silica catalysts (→ Polyolefins, Chap. 1.3.2.1.) or Ziegler – Natta catalysts based on titanium chloride or vanadium catalysts (→ Polyolefins, Chap. 1.3.2.2.). These traditional catalysts have several chemically different active sites, each of which produce polymer of slightly different composition. As a result, these catalysts produce a bulk polymer that has a moderately broad to very broad molecular mass distribution (MMD). When producing ethylene – α-olefin copolymers, the different sites also have different affinities for the comonomer (α-olefin). Thus, copolymers made with Ziegler – Natta or chromium on silica catalysts also have a broad composition distribution. Typically, the comonomer is preferentially incorporated into the lower molecular mass molecules of the bulk polymer when using these traditional catalysts.

In contrast, transition metal – MAO catalysts are molecular catalysts and produce polymers of much narrower MMD and composition distribution. As a result, this family of catalysts is often referred to as "single site" catalysts, regardless if the transition metal compound is a zirconocene derivative, another metallocene, a "half-sandwich" complex such as the Dow "constrained geometry" catalyst [61], or a nickel catalyst [95]. (The label "single site", however, is a misnomer. Only solution catalysts that utilize high MAO aluminum to transition metal ratios are truly single site and produce polymer with a single Flory distribution. Most metallocene – MAO catalysts, especially heterogeneous catalysts supported on a carrier such as silica, produce polymer that has multiple Flory distributions [74].)

The first high volume industrial use of metallocene – MAO catalyst has been in the production of polyethylene, particularly linear low density polyethylene (LLDPE). The narrower MWD and composition distribution ultimately translate to a polymer that has higher impact strength, lower extractable components, better clarity, and better heat sealing properties than polymer made from traditional catalysts [75].

Likewise, ethylene – α-olefin copolymers can be made with much higher comonomer levels from metallocene catalysts than from Ziegler – Natta catalysts. These polymers have application in the plastomers and elastomers markets [76].

Isotactic polypropylene can be made industrially using MAO with derivatives of the *ansa*-zirconocene compound, *rac*-$EtInd_2ZrCl_2$ described above [77]. Derivatives of the MAO – $[Me_2Si(Cp)(Flu)ZrCl_2]$ (Flu = fluorenyl, η^5-$C_5H(C_4H_4)_2$) catalyst system produce syndiotactic polypropylene [78]. Isotactic polypropylenes produced by metallocene – MAO catalysts tend to have narrower MMD and higher isotactic index than those polymers produced by traditional catalysts.

Synthetic rubbers, which are terpolymers of ethylene, propylene, and either 1,4-butadiene or 2-ethylidenenorbornene (EPDMs) (→ Metallocenes, Chap. 2.; → Rubber, 3. Synthetic, Chap. 3.2.2.) can also be produced by zirconocene – MAO catalysts [79].

$CpTiCl_3$ or its derivatives and MAO catalyst systems are used commercially to produce syndiotactic polystyrene [80].

It has been reported that zirconocene derivatives or nickel catalysts can be used with an aluminoxane cocatalyst to produce linear α-olefins [81], [82]. Neither of these systems, however, has yet been commercialized.

Metallocene – aluminoxane catalysts are used industrially in high-pressure autoclave, solution, slurry, and gas-phase polymerization processes. These catalyst systems are used as both in homogeneous solutions and supported on a carrier such as silica.

3.4. Analysis and Quality Specifications

Alkylaluminum compounds have traditionally been analyzed to determine aluminum content, the molar ratio of alkyl groups to aluminum, and the identity of the alkyl groups and/or halides bonded to aluminum. The ratio and identity of alkyl groups is determined by hydrolysis of the alkylaluminum compound and gas chromatography analysis of the hydrolysis gases. MAO has also been analyzed and characterized using these techniques: aluminum content by titration and methyl group to aluminum ratio by digestion methods.

NMR has been used to detect and determine the presence of other species such as aluminum hydrides and other low level impurities in alkylaluminums. NMR of MAO reveals that there is always some residual TMA present in MAO. Indeed, NMR can be used to determine the absolute amounts of TMA and MAO in MAO product, as well as the methyl to aluminum ratio [59]. For this, NMR is superior to titration techniques which measure "acidic aluminum" and tend to overestimate the amount of TMA and consequently underestimate the amount of MAO.

MAO is a performance product: its quality is best measured in how well it performs in a given catalyst system. Specifications based on percent aluminum in solution, percent TMA, percent MAO and methyl to aluminum ratio are used and are useful to measure how consistent the manufacture of MAO is. MAO is still not well understood enough, however, to directly measure its critical features that relate to product quality.

4. Handling, Storage, and Transportation

In view of the reactivity of the industrially useful organoaluminum materials with air and water, much effort has been expended in developing special shipping, handling, and storage procedures (e.g., see merchant brochures in reference [83], [84]).

Organoaluminum materials generally are protected with an inert nitrogen atmosphere. Low moisture ($< 3.5\,mg/m^3$) and oxygen (< 0.001 vol %) contents are recommended. Activity toward air of the organoaluminum materials is decreased by dilution with inert solvents (e.g., aliphatic or aromatic hydrocarbons).

Chlorinated solvents should be avoided with organoaluminum compounds. Alkylaluminums react with polyhalogenated organic solvents, such as chloroform or carbon tetrachloride, to form unstable intermediates, especially at high temperature [85].

For shipping purposes, organoaluminum materials are classed as spontaneously combustible liquids or, in the case of some dilute solutions, as water-reactive, flammable liquids. This classification depends on the performance of the blend in certain tests. For an example of a test, see [86].

Portable steel shipping tanks range in size from small metal cylinders for laboratory and pilot-plant studies to ones with $7.5\,m^3$ capacity (Fig. 6). In addition, shipments are made in tank trailers and rail tank cars in the United States and in some other countries.

International shipments of organoaluminum products in portable tanks are made according to the United Nations Transport of Dangerous Goods Code, wherein they are listed in Table 12.2 [87]. The products appear in the International Maritime Organization IMO-IMDG code portable tank tables under their UN numbers [88]. Alkylaluminums and alkylaluminum halides are identified, respectively, by UN 3051 and UN 3052. Non-pyrophoric alkylaluminum blends and MAO are identified by UN 3207.

In Europe, international agreements cover transport of organoaluminum materials by rail (RID) [89] and by road (ADR) [90], under Class 4.2 and 4.3, Appendix X in both cases. In the United States, they are shipped according to U.S. Department of Transportation (DOT) regulations 49 CFR 173.124 (c) and 173.125 for organometallic compound solutions, water-reactive, flammable and 173.124 (b) (1) and 173.125 for spontaneously combustible liquids [91].

Handling and storage facilities are designed with safe flushing and cleaning in mind, and can be protected from air by a continuous nitrogen flow through the equipment and out through an oil seal drum, under a positive pressure with respect to the outside atmosphere [83], [84], [92]. Fire walls are provided for operator safety and equipment protection. Concrete pads, sloping to a fire-safe area, are recommended under tanks in the plant.

Should lines and tanks in organoaluminum service require cleaning, extreme caution is urged during the cleaning process. A buildup of solids may result from accidental thermal, oxidative, or hydrolytic decompositions. The equipment is cleaned by a combination of inert solvent flushing, steam, water, and an aqueous caustic solution (< 25 wt %). A nitrogen purge must be maintained on the equipment during each stage of the cleaning process to safely vent hydrogen and volatile hydrocarbons that may form.

Spills of organoaluminum materials or their hydrocarbon solutions present special hazards.

Figure 6. Portable shipping tank used by Albemarle Corporation
Dimensions, (in cm) A 304.5; B 190.0; C 224.0; D 140.0

Tare	2880 kg
Design pressure	12.31 kg/cm^2
Relief valve set pressure	12.31 kg/cm^2
Cubage	13.0 m^3

a) Recessed dome; b) 3/4″ Vapor space connection for nitrogen and vent; c) 1 1/2″ Dip pipe for liquid removal; d) Tie down and towing ring; e) Lifting lugs (4); f) Lloyd's stamp; g) Relief valves (2); h) ASME nameplate; i) DOT nameplate; j) Owner's nameplate; k) Dutch Railroad nameplate; l) Fork lift openings; m) Skids for handling

There is, of course, a danger of spontaneous flaming. Even in the absence of fire, hydrogen, hydrocarbon vapors, and hydrogen halides may be released.

For small, contained spills, absorption in dry powder extinguishing agents or blanketing with vermiculite may be used. Once absorbed or blanketed, the materials may be deactivated by slow aging in air, or by controlled burning.

Dry powder fire extinguishers are effective in the control of small to moderate sized fires resulting from a spill of undiluted or solutions of organoaluminum compounds [93]. Carbon dioxide is somewhat effective on solution fires, but less effective on fires of undiluted organoaluminum compounds. For larger fires, in isolated regions, controlled burning may be the best approach. Application of a water fog has been found effective in alkylaluminum fire control in plant process areas. Water fog systems have been installed in some alkylaluminum handling and reaction systems [83].

The amount and type of personal protective equipment recommended depend on the magnitude of potential exposure [83], [84]. Fire retardant clothing, with long sleeves, face shield, and nonporous gloves that can be removed quickly is suggested when working in the laboratory with small quantities. For larger potential exposure, full suits made of aluminized, fire-resistant material are worn, along with goggles and a hood for head protection, heat-resistant gloves, and combination spats and shoe covers or heavy leather or rubber boots to protect legs and feet.

5. Waste Disposal and Environmental Protection

Some organoaluminum compounds are extremely sensitive to oxygen or water and may spontaneously burst into flames in their presence.

Small amounts of residues from laboratory-scale organoaluminum syntheses or reactions generally can be deactivated to air or moisture by dilution with a hydrocarbon solvent under an inert atmosphere, followed by protonolysis with an alcohol, such as isopropyl alcohol. Finally, water can be added carefully until no further reaction is observed. Larger volumes can be destroyed by incineration. Disposal of the ash from incineration, consisting mainly of metal oxides, should be handled in a manner that is consistent

with all local, state, and federal regulations and environmental laws.

Hydrolysis, under acidic or basic conditions, is an effective method for the destruction of organoaluminum compounds. The alkyl waste should be diluted with a high flash point, low vapor pressure diluent to a metal concentration of less than 5 wt % prior to hydrolysis [83], [84].

Organoaluminum materials produce no unexpected environmental effects. Once in contact with the atmosphere or soil, either they degrade rapidly to hydrocarbons and inorganic products, or, on flaming, they burn to form the expected combustion products.

6. Economic Aspects

Merchant producers of organoaluminum products for industrial use include Albemarle Corp., with plants in Houston, Tex. and Orangeburg, S. C., USA, and Feluy, Belgium; Akzo Nobel, Deer Park, TX, USA and Rotterdam, The Netherlands; Nippon Aluminum Alkyls Ltd., Osaka, Japan; Tosoh Akzo Chemical Co., Yamaguchi, Japan; and Witco AG, Bergkamen, Germany and Mapleton, IL, USA. In addition there is considerable "captive use" production by a number of companies, for making polyolefin catalysts and for intermediates in the synthesis of organic and organometallic products.

Capacity, production, and total consumption figures for organoaluminum materials are not published.

7. Toxicology and Occupational Health

The effects of organoaluminum compounds on the skin can range from a slight irritation to a severe burn, depending on concentration. These burns generally are treated in the same manner as thermal burns; in all cases, the affected areas should be flushed immediately with water.

Breathing fumes produced by organoaluminum materials in contact with air or combustion products from the burning materials should be avoided. Effects of the combustion products on humans are essentially the same as effects of smoke from the burning of organic substances. In addition, "fume fever" may result from prolonged breathing of the aluminum-containing particulate matter. The threshold limit values (TLVs) in air of "Aluminum, alkyls (NOC)" are described by the ACGIH and the NIOSH. A time-weighted average (TWA) for a normal 8-h workday of 2 mg/m^3 of airborne particulate matter, expressed as aluminum, is specified [94], [95].

Acknowledgments

The authors would like to thank Drs. Tom Hanlon, Won Park, Steven Herron, and Ray Dawson for helpful suggestions and comments.

1. General Aspects

Almost 4000 years ago Egyptians and Babylonians used aluminum compounds in various chemicals and medicines. Herodotus mentioned alum in the fifth century B.C. and Pliny referred to "alumen," now known as alum, as a mordant to fix dyes to textiles around 80 A.D. In 1754 Marggraf showed that a distinct compound existed in both alum and clays. In 1761 the French chemist Guyton de Morveau proposed the name "alumine" for the base in alum, identified in 1787 by Antoine Lavosier as the oxide of a then-undiscovered element. By the 1700s the earthy base alumina was recognized as the potential source of a metallic element.

Greville (1798) described a mineral from India that had the composition Al_2O_3 and named it corundum [*1302-74-5*], derived from the native name of this stone. Haüy (1801) called a mineral diaspore [*14457-84-2*] (from the Greek "diaspora" meaning dispersion) because it decrepitated on heating. Its composition, $Al_2O_3 \cdot H_2O$, was determined by Vaquelin in 1802. Gibbsite [*14762-49-3*], named after the American mineralogist G. Gibbs, was found

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a01_557

by DEWEY in 1820; TORREY (1822) showed this mineral to have the composition $Al_2O_3 \cdot 3\,H_2O$. The name hydrargillite [*14762-49-3*] was given to a similar mineral found later in the Ural Mountains. Using the newly developed technique of X-ray diffraction, BÖHM and NICLASSEN [13] identified a crystalline aluminum oxide hydroxide, $Al_2O_3 \cdot H_2O$, later named böhmite (boehmite). BÖHM discovered a second type of trihydroxide, $Al_2O_3 \cdot 3\,H_2O$, a year later. FRICKE [14] suggested the name bayerite [*20257-20-9*] for this compound, believing it to be the product of the Bayer process, which he later identified as gibbsite. Only few occurrences of natural bayerite have been reported [15]. VAN NORDSTRAND et al. [16] reported a third form of trihydroxide, which was later named nordstrandite [*13840-05-6*] in his honor.

1.1. Aluminum Hydroxides

A general classification of the various modifications of aluminum hydroxides is shown in Figure 1. The best defined *crystalline forms* are the three trihydroxides, $Al(OH)_3$: gibbsite, bayerite, and nordstrandite, and two modifications of aluminum oxide hydroxide, AlO(OH): boehmite and diaspore. Besides these well-defined crystalline phases, several other forms have been described in the literature [2], [3]. However, there is controversy as to whether they are truly new phases or simply forms with distorted lattices containing adsorbed or interlamellar water and impurities.

Identification of the different hydroxides and oxides is best carried out by X-ray diffraction methods [3]. Mineralogical and structural data are listed in Tables 1 and 2.

Gelatinous hydroxides may consist of predominantly X-ray indifferent aluminum hydroxide or pseudoboehmite. The X-ray diffraction pattern of the latter shows broad bands that coincide with strong reflections of the well-crystallized oxide hydroxide boehmite.

The aluminum hydroxides found abundantly in nature are gibbsite, boehmite, and diaspore. *Gibbsite* and *bayerite* have similar structures. Their lattices are built of layers of anion octahedra in which aluminum occupies two thirds of the octahedral interstices. In the gibbsite structure, the layers are somewhat displaced relative to one another in the direction of the *a* axis. The hexagonal symmetry of this lattice type (brucite type) is lowered to monoclinic. Triclinic symmetry was found in larger gibbsite single crystals from the Ural Mountains [17].

In bayerite the layers are arranged in approximately hexagonal close packing. Because of shorter distances between the layers, the density is higher than in the case of gibbsite. The crystal class and space group of bayerite have not yet been established clearly.

The individual layers of hydroxyl ion octahedra in both the gibbsite and the bayerite structures are linked to one another only through weak hydrogen bonds. Bayerite does not form large single crystals. The most commonly observed growth forms are spindle- or hourglass-shaped somatoids. The long axis of these somatoids stands normal to the basal plane; i.e., the somatoids consist of stacks of $Al(OH)_3$ layers (Fig. 2). The effect of alkali ions on the structures of $Al(OH)_3$ types was investigated by several workers [3], [18], [19]. Intercalation of Li^+ ions transforms gibbsite to the hydrotalcite structure [20].

Figure 2. Somatoids of bayerite

Gibbsite crystals of appreciable size are not uncommon. Clear pseudohexagonal platelets about 1 mm in diameter are known from Arö in Norway. Prismatic crystals 0.5 – 1 mm in length are occasionally produced in the Bayer process.

Nordstrandite, the third form of $Al(OH)_3$, was described by VAN NORDSTRAND [16] and others [21]. The structures of nordstrandite and bayerite were investigated [22] and compared with those of monoclinic and triclinic gibbsite, which had been determined previously [17].

Figure 1. Classification of aluminum hydroxides
(All figures courtesy of Aluminum Company of America)

Table 1. Mineralogic properties of oxides and hydroxides [3]

Phase	Refractive index n_D^{20}				Cleavage	Brittleness	Mohs hardness	Luster
	α	β	γ	Average				
Gibbsite	1.568	1.568	1.587	–	(001) perfect	tough	2.5 to 3.5	pearly vitreous
Bayerite	–	–	–	1.583	–	–	–	–
Boehmite	1.649	1.659	1.665	–	(010)	–	3.5 to 4	–
Diaspore	1.702	1.722	1.750	–	(010) perfect	brittle	6.5 to 7	brilliant pearly
	ε	ω		Average				
Corundum	1.7604	1.7686		–	none	tough when compact	9	pearly adamantine

The lattice of nordstrandite is built of the same, electrically neutral $Al(OH)_3$ octahedral layers that form the structural elements of gibbsite and bayerite [14]. The lattice period amounts to 1.911 nm in the direction normal to the layer. This corresponds to the sum of identical layer distances of bayerite plus gibbsite. The identical nordstrandite structure consists of alternating double layers, in which the OH octahedra are arranged once in the packing sequence of bayerite, and then in that of gibbsite. Material containing continuous transitions from bayerite through nordstrandite to gibbsite has been prepared through the proper selection of precipitation conditions [18].

1.2. Aluminum Oxide Hydroxides

Pseudoboehmite is formed during aging of X-ray indifferent hydroxide gels as a precursor of trihydroxide. The reflections of pseudoboehmite are broadened not only because of the very small particle size, but also because of variable distances of the AlO(OH) double chains, which form the structural element of pseudoboehmite as well as of well-crystallized boehmite. The lattice spacing in the direction of the *c* axis increases by 0.117 nm for each mole of excess water [22].

Boehmite consists of O, OH double layers in which the anions are in cubic packing.

Table 2. Structural properties of oxides and hydroxides [3]

Phase	Formula	Crystal system	Space group	Molecules per unit cell	Unit axis length, $\times 10^{-1}$ nm			Angle	Density, g/cm^3
					a	*b*	*c*		
Gibbsite	$Al(OH)_3$	monoclinic	C_{2h}^5	4	8.68	5.07	9.72	94°34′	2.42
Gibbsite	$Al(OH)_3$	triclinic	–	16	17.33	10.08	9.73	94°10′ 92°08′ 90°0′	–
Bayerite	$Al(OH)_3$	monoclinic	C_{2h}^5	2	5.06	8.67	4.71	90°16′	2.53
Nordstrandite	$Al(OH)_3$	triclinic	C_i^1	4	8.75	5.07	10.24	109°20′ 97°40′ 88°20′	–
Boehmite	AlO(OH)	orthorhombic	D_{2h}^{17}	2	2.868	12.227	3.700	–	3.01
Diaspore	AlO(OH)	orthorhombic	D_{2h}^{16}	2	4.396	9.426	2.844	–	3.44
Corundum	Al_2O_3	hexagonal (rhomb.)	D_{3d}^6	2	4.758	–	12.991	–	3.98

The aluminum ions are octahedrically coordinated. These layers are composed of chains of $[AlO(OH)]_2$ extending in the direction of the *a* axis [23]. The double layers are linked by hydrogen bonds between hydroxyl ions in adjacent planes. Boehmite crystals exhibit perfect cleavage parallel to the (010) plane.

In the *diaspore* structure the oxygen ions are nearly equivalent, each being joined to another oxygen center through a hydrogen ion. The anions are hexagonally close packed [24]. The position of the hydrogen ion has been established by neutron diffraction [25]. The O – H – O distance is 0.265 nm. By infrared studies, the bond energy for the hydrogen bridges in diaspore was determined to be 28.7 kJ/mol, compared with 20.1 kJ/mol for boehmite [26].

1.3. Aluminum Oxide, Corundum

The hexagonally closest packed α-Al_2O_3 modification is the only stable oxide in the $Al_2O_3 - H_2O$ system. Corundum is a common mineral in igneous and metamorphic rocks. Red and blue varieties of gem quality are called ruby and sapphire, respectively. The lattice of corundum is composed of hexagonally closest packed oxygen ions forming layers parallel to the (0001) plane. Only two-thirds of the octahedral interstices are occupied by aluminum ions. The structure may be described roughly as consisting of alternating layers of Al and O ions. The corundum structure was determined in the early 1920s [27]; numerous workers later confirmed and refined these data [3]. Properties of corundum are listed in Tables 1 and 2.

1.4. The $Al_2O_3 - H_2O$ System

Under the equilibrium vapor pressure of water, crystalline $Al(OH)_3$ converts to AlO(OH) at about 375 K. The conversion temperature appears to be the same for all three forms of $Al(OH)_3$. At temperatures lower than 575 K, boehmite is the prevailing AlO(OH) modification, unless diaspore seed is present. Spontaneous nucleation of diaspore requires temperatures in excess of 575 K and pressures higher than 20 MPa. In the older literature, therefore, diaspore was considered the high-temperature form of AlO(OH). The first reaction diagram of the phase transitions in the $Al_2O_3 - H_2O$ system was published in 1943 [28]. These workers determined the gibbsite $\rightarrow$ boehmite conversion temperature to be 428 K. Boehmite transformed to diaspore above 550 K; diaspore converted to corundum, α-Al_2O_3, at 725 K. Similar results were reported in 1951 [29].

The system was reinvestigated in 1959 [30] and in 1965 [31]. A phase diagram based on these data is shown in Figure 3. Diaspore is

the stable modification of AlO(OH); boehmite is considered metastable, although it is kinetically favored at lower temperatures and pressures. This is because the nucleation energy is lower for boehmite than for the considerably more dense diaspore. Nucleation is additionally facilitated by the possibility that boehmite can grow epitaxially on $Al(OH)_3$. In the $Al_2O_3 - Fe_2O_3 - H_2O$ system, the presence of the isostructural goethite, α-FeO(OH), lowers the nucleation energy for diaspore so that this AlO(OH) modification crystallizes at temperatures near 373 K [32]. This observation explains the occurrence of diaspore in clays and bauxite deposits that have never been subjected to high temperatures or pressures.

Figure 3. The $Al_2O_3 - H_2O$ system
Dashed lines [21], solid lines [22], [28]

Nomenclature. Although there is fairly good agreement in the more recent literature on phase fields and structures of the crystalline phases in the $Al_2O_3 - H_2O$ system, the nomenclature is still rather unsystematic.

Bayerite, gibbsite (hydrargillite), and nordstrandite are trihydroxides of aluminum, and not oxide hydrates. The designation "aluminum oxide monohydrate" for boehmite and diaspore is also incorrect. Both are true oxide hydroxides. Molecular water has been determined only in poorly crystallized, nonstoichiometric pseudoboehmite.

The designation of the modifications of aluminum hydroxides and oxides lacks uniformity just as much as does the nomenclature of the compounds. According to the general usage in crystallography, the most densely packed structures are designated as α-modifications [3]. Bayerite, diaspore, and corundum fall within this class. The compounds with cubic packing sequence, gibbsite and boehmite, have been designated by the symbol γ. Nordstrandite can be classified as β-$Al(OH)_3$ when regarding this compound not as an intergrowth of bayerite and gibbsite, but as an independent modification.

1.5. Thermal Decomposition of Aluminum Hydroxides

When aluminum hydroxides or oxide hydroxides are heated in air at atmospheric pressure, they undergo a series of compositional and structural changes before ultimately being converted to α-Al_2O_3. These thermal transformations are topotactic. Despite a loss of 34 or 15 % of mass for the trihydroxides or oxide hydroxides, respectively, the habit of the primary crystals and crystal aggregates changes very little. This leads to considerable internal porosity, which may increase the specific surface area of the material to several hundred m^2/g. Structural forms develop that, although not thermodynamically stable, are well reproducible and characteristic for a given temperature range and starting material. These transition aluminas have been the subject of numerous investigations because of their surface activity, sorptive capacity, and usefulness in heterogeneous catalysis. The literature in this field of physical chemistry has been reviewed up to 1987 [3].

The simplest transformation is that of diaspore to corundum. As the structures of these two compounds are very similar, the nucleation of α-Al_2O_3 requires only minor rearrangement of the oxygen lattice after the hydrogen bonds are broken. A temperature below 860 – 870 K is sufficient for complete conversion. The newly formed corundum grows epitaxially on the decomposing diaspore, with the (0001) plane of Al_2O_3 parallel to the (010) plane of AlO(OH) [33]. Transformation to corundum (α-Al_2O_3) proceeds through an intermediate α'-Al_2O_3 phase [34].

Figure 4. Gibbsite heated to 573 K

Figure 5. Specific surface area, loss on ignition (LOI), and density of heated $Al(OH)_3$

The thermal transformation, at ambient pressure, of boehmite and the trihydroxides to α-Al_2O_3 requires considerably more structural rearrangements and is generally not completed until the temperature reaches at least 1375 – 1400 K. The first step in the reaction sequence is the diffusion of protons to adjacent OH groups and the subsequent formation of water [35], [36]. This process begins at a temperature near 475 K. If this water cannot diffuse rapidly out of larger trihydroxide particles, hydrothermal conditions may develop locally, resulting in the formation of γ-AlO(OH). With increasing loss of water, a large internal porosity develops. The lattice voids left by the escaping water are not readily healed because of the slow diffusion in this low temperature range. The voids are oriented parallel and perpendicular to the basal plane of the trihydroxide crystals (Fig. 4).

The highest surface area and lowest crystalline order of the solid (not counting newly formed boehmite) is obtained at a temperature around 675 K. With increasing temperature the surface area decreases, while the density of the solid shows progressively higher values (Fig. 5). This trend is the result of progressive reordering and consolidation of the solid.

During the thermally driven consolidation and reordering, the solid goes through structural stages that are influenced by the nature of the starting material as well as by heating rates, furnace atmosphere, and impurities. The general reaction paths are illustrated in Figure 6, which shows the various intermediate transition forms that have been identified during the reordering process.

Figure 6. Decomposition sequence of aluminum hydroxide

Transition oxides formed at lower temperatures are mostly two-dimensional, short-range ordered domains within the texture of the decomposed hydroxides. Extensive three-dimensional ordering begins at about 1050 K. Until completely converted to corundum, the solid retains considerable amounts of OH^- ions. Most likely protons are retained to maintain electroneutrality in areas deficient of cations. Therefore, the presence of protons may retard the reordering of the cation sublattice. The high surface area ($> 75\,m^2/g$) of γ-Al_2O_3 has been shown to provide thermodynamic stability [37]. Addition of fluorine to the furnace atmosphere removes protons. As a result, rapid transition to α-Al_2O_3 occurs at temperatures as low as

1150 K. Markedly tabular corundum crystals form, possibly because the preceding transition alumina is mostly two-dimensionally ordered [38].

Transition forms other than those shown in Figure 6 can be obtained by hydrothermal treatment [3]. The structures of various transition forms have been investigated [17], [22], [39].

1.6. Aluminates and Related Compounds

Sodium oxide forms several compounds with aluminum oxide. These so-called β-aluminas represent a group of aluminates having the same, or very similar, structures but variable chemical composition. Their molar ratios ($Na_2O : Al_2O_3$) can vary between 1 : 1 and 1 : 11. The 1 : 1 sodium aluminate, $NaAlO_2$ [*1302-42-7*], exists in at least two allotropic modifications. Orthorhombic β-$NaAlO_2$ is stable below 750 K; the higher – temperature γ modification is tetragonal. For preparation and properties of technical sodium aluminate, → Aluminum Compounds, Inorganic, Chap. 2.1.

The 1 : 11 β-Al_2O_3 crystallizes from melts containing aluminum oxide and sodium oxide or other sodium compounds. A 1 : 5 β-alumina has been prepared by heating α-Al_2O_3 with $NaAlO_2$ or Na_2CO_3 at about 1325 K.

Several other β-aluminas containing CaO, BaO, or SrO in 1 : 6 ratio also have been reported [3].

β-Alumina is of interest to its use as a solid electrolyte in sodium – sulfur secondary batteries (→ Batteries).

2. Bauxite, the Principal Raw Material

2.1. Definition and Geology

The term bauxite [*1318-16-7*] is used for sedimentary rocks that contain economically recoverable quantities of the aluminum minerals gibbsite, boehmite, and diaspore. The name derives from the description by BERTHIER, in 1821, of a sediment that occurred near the village of Les Baux in the Provence, France. Originally assumed to be a dihydrate of aluminum oxide, bauxite was later recognized as being composed of aluminum hydroxide, iron oxide and hydroxide, titanium dioxide, and aluminosilicate minerals [2].

Early in this century, major bauxite deposits were found in various parts of the Tertiary and Cretaceous limestone formations of the European Alps; also in several locations on the North American continent, e.g., in Arkansas, Alabama, and Georgia. Since the 1920s, extensive deposits have been discovered in the tropical and subtropical climate belts.

The oldest known bauxites developed in the Precambrian; the youngest are of recent origin. Deposits may occur as extensive, flat bodies blanketing areas of many square miles; they may form irregularly shaped fillings of dolinas in old karst surfaces, or lenses several hundred meters in diameter and tens of meters thick. Allochtonous, i.e., displaced bauxites, are also common; erosion of primary deposits and redeposition of the detritus in valleys or along mountain slopes has frequently led to mineable accumulations of ore.

Many of the geologically younger bauxites are covered only by thin layers of soil; others are buried by coastal or alluvial sediments. Older deposits, especially in the Balkans or the Ural Mountains, often are overlain by carbonate rocks hundreds of meters thick. Regardless of their geologic age, all bauxites were formed during continental periods [40].

2.2. Composition and Properties

The chemical composition of bauxites of various origin is given in Table 3 [2]. Aluminum oxide, iron oxide, and titanium and silicon dioxides are the major chemical components of all bauxites. Alkali and alkaline earth compounds are rarely found.

Gibbsite, γ-$Al(OH)_3$, is the predominant aluminum mineral in the geologically young bauxites of the tropical climate belt. Mesozoic and older bauxite contain mostly boehmite (γ-AlO(OH)) or diaspore (α-AlO(OH)). Since their formation, many of the older bauxites have been buried under considerable layers of younger sediments and often were subjected to tectonic stress. Boehmite and diaspore formation appears

Table 3. Principal chemical constituents of various bauxites, wt %

to be related to an increasing degree of metamorphism. However, both minerals also occur in young deposits, although in minor quantities. The chemical environment obviously plays as important a role in the formation of boehmite and diaspore as do pressure and stress [40].

Dissolution of gibbsite requires the mildest conditions in the Bayer process (see Section 3.1.2). Higher temperatures and alkali concentrations are necessary for the digestion of boehmite and diaspore. Technically, both oxide hydroxides can be processed without difficulties. The abundance of high-grade gibbsitic bauxites, however, has made boehmite- and diaspore-rich ores economically less attractive.

Goethite, α-FeO(OH) [*1310-14-1*], and hematite, α-Fe_2O_3 [*1309-37-1*], are the most prevalent iron minerals in bauxites. They are practically inert under the conditions of the Bayer process. In both materials, some of the iron may be replaced isomorphically by aluminum ions. This amount of aluminum is included in the chemical analysis of the bauxite but is normally not extracted in the digest. Magnetite (Fe_3O_4) is found in some European bauxites; pyrite (FeS_2) and siderite ($FeCO_3$) also may occur. Decomposition of pyrite may lead to high sulfur levels in the process solutions.

Anatase, TiO_2 [*1317-70-0*], is the titanium mineral found most frequently in bauxites. Rutile, TiO_2 [*1317-80-2*], occurs in some European

deposits; $FeTiO_3$ is also present in minor quantities, especially in titanium-rich bauxites. Titanium dioxide minerals are attacked under only the most severe conditions of the Bayer process.

Silicon dioxide may occur as quartz [*14808-60-7*], as in the bauxites of the Darling Range in Western Australia. Most commonly, however, SiO_2 is associated with the clay minerals kaolinite, halloysite, or montmorillonite. These aluminosilicates react with sodium aluminate solutions to form insoluble sodium aluminum silicates during digest, causing loss of sodium hydroxide and extractable alumina. The amount of so-called reactive silica is one of the major factors determining quality and price of the ore.

Minor constituents, such as chromium, vanadium, zinc, and gallium, have little effect on the Bayer process or on the quality of the final product. Some tend to accumulate in the recirculated process solutions (e.g., gallium and vanadium) and must be removed periodically by appropriate treatments.

The physical properties of bauxites, i.e., texture, hardness, and density, can vary widely. Geologically old diaspore bauxites, especially those high in iron oxide, are very hard and can reach densities of 3.6 g/cm^3. Young tropical deposits, in contrast, may have an earthy, soft texture and a density around 2.0 – 2.5 g/cm^3. Allochtonous bauxite often consists of hard nodules embedded in a soft, usually clayey matrix. Porous textures also occur. The color of bauxites is largely determined by the type and particle size of the prevalent iron mineral. Highly dispersed goethite tends to be yellow to orange, whereas dark brown tones usually are associated with coarser hematite. Colors can vary greatly within a single ore body.

Hardness, texture, and the amount of overburden determine the methods applied for bauxite mining. Deposits in Greece, former Yugoslavia, Hungary, and the former Soviet Union require deep mining to depths of several hundred meters, often complicated by the difficulties of controlling water levels in the porous limestone formations. Tropical bauxites frequently are located so close to the surface that they can be recovered with normal earth-moving equipment.

2.3. Genesis of Bauxites

Many of the geologically young bauxite deposits are located in the savannah region, which extends north and south of the tropical rain forest belt. The climate of this region is characterized by a high mean annual temperature and abundant precipitation during the rainy season. Deposits occur on gently sloping hills or on peneplains. The stratigraphic evidence shows that these bauxites have formed in situ. Parent rocks may be coarse-grained, igneous rocks such as syenite, phonolite, basalt, or gabbro. However, large deposits also developed on kaolinitic sandstones, on phyllites, and on schists. A layer of kaolinitic clay is frequently found between the ore body and the parent rock.

Bauxite probably forms during long periods of low geologic activity when the combination of high temperature, abundant precipitation, and good vertical drainage favors intensive chemical weathering. The sequence of leaching begins with removal of alkali followed by the removal of alkaline earths. Oxides of iron, aluminum, titanium, and silicon are mobilized and reprecipitated as hydroxides and oxides. Aluminum hydroxide and silica form kaolinite, $Al_4(OH)_8Si_4O_{10}$. This sequence first leads to the formation of tropical soils (laterites). Bauxitization follows when the climatic, chemical, and topographic conditions prevail long enough to allow the removal of silicon dioxide as well.

The bauxite deposits of the Mediterranean region, the Caribbean Islands, and many other locations that are associated with tertiary and older limestone formations (karst bauxites) were formed by a similar weathering process. Parent materials were lateritic soils and clays transported into the karst region and deposited in depressions. During extended terrestrial periods, high mean temperatures, copious precipitation, and good vertical draining through the porous limestone bedrock facilitated a thorough desilification. In the older literature, the parent material for karst bauxitization was reported to be clayey residue left after weathering of substantial layers of carbonate rocks [41]. Researchers have shown conclusively that igneous rocks were the source of this material [42–44].

Comprehensive reviews on the geology, mineralogy, and genesis of bauxites have been published [40], [45].

Table 4. World bauxite reserves and production, 10^3 t [46]

Country	Mine production		Reserves

2.4. Major Bauxite Deposits

Until the 1950s, the European aluminum industry was supplied from the karst bauxite deposits of France, Hungary, former Yugoslavia, and Greece. United States sources (Arkansas) and ore from Surinam provided the raw material for North American production. Since then, the picture has changed dramatically. The four largest bauxite producers of 1990, namely, Australia, Guinea, Jamaica, and Brazil (Table 4), hardly would have been mentioned in 1950. Today, they provide more than half of the world's total bauxite output.

Africa. The Savannah region covers an area of the African continent that has experienced low geologic activity for a long time. In this belt, which stretches from the Ivory Coast to Madagascar, very large bauxite deposits were found. The major production is currently concentrated in Guinea and Ghana. Cameroon, Sierra Leone, Mali, and the Congo region, among other areas, have substantial reserves.

Australia. Major deposits are located in the Darling Range in Western Australia, on the Gove Peninsula in the Northern Territory, and on the Cape York Peninsula in Queensland. Bauxite also occurs in New South Wales, in Victoria, and on the island of Tasmania. The Australian deposits developed between the Eocene and Pliocene epochs on substrates ranging from Precambrian sandstones to Tertiary basalts. Gibbsite is the predominant aluminum mineral, although some boehmite occurs in all but the Western Australian deposits.

South America. On the outer slopes of the old Guyana Shield, many economically important deposits have been found. They are located in the Amazon Basin of Brazil, in Colombia, Venezuela, Surinam, Guyana, and French Guyana. Surinam and Guyana have been producing for more than 60 years, whereas the Brazilian Amazon deposits have been mined only recently. Bauxite also is produced in the Pocos de Caldas area in Southern Brazil, state of Minas Gerais. The South American bauxites generally are geologically young, gibbsitic ores.

Caribbean. Jamaica and the Dominican Republic have major reserves of karst bauxites that occur on Tertiary limestones under generally very thin overburden. Although gibbsite is the main aluminum mineral, some boehmite also is present. Jamaica has been one of the world's leading bauxite producers for the past 20 years.

North America. The only economically important deposit is located in Arkansas, where gibbsitic bauxite developed on nepheline syenite during the Eocene. Less than 5×10^7 t of bauxite remain, and the grade is declining.

Europe. Except for a few commercially insignificant occurrences, all European bauxites are of the karst type. The oldest deposits (Devonian/Mississippian) are those of the Tikhvin area in the former Soviet Union; the youngest are the Eocene bauxites of former Yugoslavia. Most European deposits developed during the Lower and Upper Cretaceous, e.g., the diaspore and boehmite bauxites of France, Greece, and Romania, and the gibbsite and boehmite bauxites found in Hungary, former Yugoslavia, and

Italy. Today, all European mines combined contribute only about 15 % of world production.

Asia. Major deposits of gibbsite bauxites occur in India; the island of Kalimantan (Indonesia) has large potential reserves. Numerous bauxite deposits, most of them containing geologically old, diaspore-rich ore, were found in China. Substantial deposits also are located in Western Siberia.

2.5. Economic Aspects

The proved reserves of bauxite shown in Table 4 are sufficient to supply the world aluminum industry for a few centuries. Total resources are estimated by the U.S. Geological Survey at 55 to 75×10^9 t. Because of the worldwide distribution of significant ore deposits, a disruption of bauxite supply for political reasons appears highly unlikely. In 1974 several major bauxite-producing nations formed the International Bauxite Association (IBA) with the intent of increasing control over the exploitation of their bauxite deposits. Although levies were increased substantially, competition from countries not associated with the IBA helped maintain a reasonable price structure.

Dissolution of gibbsite requires the mildest conditions in the Bayer process (see Section 3.1.2). Higher temperatures and alkali concentrations are necessary for the digestion of boehmite and diaspore. Technically, both oxide hydroxides can be processed without difficulty. The abundance of high-grade gibbsitic bauxites, however, has made boehmite- and diaspore-rich ores economically less attractive.

Economic and political considerations favor refining of bauxite near the deposit and shipment of either alumina or aluminum ingot. Brazil, Surinam, and Australia have smelters, although their refining capacity by far exceeds the demands of domestic metal production. Jamaica and Guinea refine a substantial portion of their own bauxite production.

About 25 % of all bauxite mined is used for producing refractories, abrasives, catalysts, adsorbents, and other industrial chemicals.

3. Bayer Process

3.1. History and Procedure

In 1855 the French mining engineer Louis le Chatelier obtained alumina from bauxite by sintering with sodium carbonate at 1200 °C and leaching the sodium aluminate with water. Aluminum hydroxide was then precipitated from the sodium aluminate solution by carbon dioxide. Early use of aluminum hydroxide was chiefly as a mordant in the textile dyeing industry. The demand for pure alumina increased rapidly when it became the raw material for aluminum production upon development of the Hall – Héroult cell. The Austrian chemist Karl Josef Bayer received German patent 43977 in August, 1888 for a new, improved process for production of aluminum hydroxide from bauxite, and the process became known as the Bayer process in his honor. Bayer initially worked on his process at the Tentelev chemical plant near St. Petersburg in Russia. Between 1888 and 1900 he supervised the construction of Bayer process plants in Germany, England, France, Italy, and the United States. The Merrimac Chemical Company in

Massachusetts first used the Bayer process in the United States, and the Alcoa plant in East St. Louis, Illinois, was constructed in 1901. Since then, plants have been built in more than 25 countries, and the present world alumina capacity is over 40×10^6 t/a (Table 5).

The important features exploited in the Bayer process are that boehmite, gibbsite, and diaspore can be dissolved in NaOH solutions under moderate hydrothermal conditions; the solubility of Al_2O_3 in NaOH is temperature dependent; most other components of the bauxite are quite inert in the process; and the silica that does dissolve subsequently forms a nearly insoluble compound. These features permit formation of a sodium aluminate solution, physical separation of the impurities, and precipitation of pure $Al(OH)_3$ from the cooled solution.

The main features of the Bayer process have remained unchanged for the last 100 years, although the scale of operations has been enlarged considerably due to chemical engineering developments. Figure 7 shows the flow sheet of the process as it is now practiced.

Each operation in the process is carried out in a variety of ways. The process begins with preparation of the bauxite by blending for uniform composition followed by grinding. In most plants the bauxite is ground while suspended in a portion of the process solution. This slurry is mixed with the balance of the heated NaOH solution, then treated in a digester vessel at well above atmospheric pressure. The digest reaction is:

$$Al(OH)_3 + Na^+ + OH^- \longrightarrow Na^+ + Al(OH)_4^-$$

Additional reactions convert impurities such as SiO_2, P_2O_5, and CO_2 to relatively insoluble compounds. The slurry leaves the digester at a temperature above its atmospheric boiling point and is cooled by flashing off steam as the pressure is reduced in several stages. The flashed steam is used to heat the slurry and the solution going to the digester. The bauxite residue solids are separated from the sodium aluminate solution in two steps so that the coarse fraction is processed separately from the fine. Both residue fractions are washed and discarded. The solution, being free of solids, is cooled and seeded with fine crystals of $Al(OH)_3$; this causes the $Al(OH)_4^-$ ions to decompose to $Al(OH)_3$, thereby reversing the reaction that previously had taken place in the digester. Again, the heat removed in cooling the solution is used to heat a colder stream in the process. After the precipitation reaction has proceeded to the point that about half of the Al_2O_3 in the solution has been removed, the mixture of solids and solution is sent to classifiers. The fine $Al(OH)_3$ particles are returned to the process to serve as seed. The coarse particles are washed and calcined to Al_2O_3. Excess solution introduced in washing the product and the residue must be removed by evaporation. In some cases the solution is treated to remove both organic and inorganic impurities before the solution is recycled through the plant.

3.1.1. Bauxite Preparation

The bauxite entering the refinery must be uniform and sufficiently fine that extraction of the Al_2O_3 and the other operations are successful. The chemical composition of bauxite varies. Uniformity is improved by blending material mined from several pits and, if necessary, by adding bauxite from storage piles. Ground bauxite cam be stpred as a slurry in surge tanks before it is pumped to digestion. These agitated tanks are operated so that plant feed is uniformly blended for several hours. Sometimes bauxites are dried to improve handling or washed to remove clay.

Hard bauxite is reduced to particles finer than 2 cm in roll or cone crushers and hammermills. Before it enters the process it is ground further to less than 0.15 cm.

Previously, fine grinding was done in dry mills operating in closed circuit with vibrating screens. Such operation required very dry bauxite to avoid blinding the screens. This resulted in a dusty working environment. In most modern plants, the bauxite is mixed with a portion of the process solution and is ground as a slurry. Rod mills and ball mills are used most frequently. The ground slurry may be passed over screens or through cyclones, with the fine particles progressing and the coarse ones being returned to the mills.

In all-wet grinding the bauxite feed and the flow of solution are controlled to keep the solids content of the slurry between 45 and 55 %. The power consumed by the mill drive is an indicator

Figure 7. Bayer process flow sheet

of the amount of grinding being done and may be used to control the feed to the mill. On a longer time scale the particle size of the product can be used to make changes in the grinding operation.

3.1.2. Digestion

In digestion, all of the Al_2O_3 in the bauxite must be extracted. A solution is produced that contains the maximum Al_2O_3 concentration that can remain stable through the rest of the process. This must be accomplished while using a minimum amount of energy.

The *conditions for digestion* can and do vary widely. The first consideration is whether the available Al_2O_3 is present as gibbsite, boehmite, diaspore, or a mixture of these minerals. The dissolution rates of the three are quite different. Generally, if the bauxite contains mixed phases, the digestion conditions will be chosen on the basis of the least soluble compound. Any $Al(OH)_3$ or AlOOH left undissolved can act as seed in the clarification step, causing precipitation of $Al(OH)_3$ while the residue is still in contact with the solution. In the *sweetening process,* boehmitic bauxite is digested under relatively mild conditions, producing an intermediate Al_2O_3 concentration. In a separate vessel, gibbsitic bauxite is added to the flow from the first digest to raise the Al_2O_3 concentration to the desired level. Another approach is

to digest only the gibbsite in a mixed bauxite. The residue is separated from the solution and redigested under more severe conditions to recover the boehmite. This method reduces the flow to the high-temperature digest and so requires lower capital and operating costs.

Figure 8. Phase diagram Na_2O–Al_2O_3–H_2O

The solubility data (Fig. 8) show that the Al_2O_3 concentration in the process solution can be increased by increasing the temperature, the NaOH concentration, or both [1–4]. As a result, operating conditions in plants vary widely. Higher digest temperatures result in higher pressures, making the equipment more expensive. There also is the need for more heat-exchange equipment, which further increases capital costs. High concentrations, on the other hand, permit increased production from a given flow rate and, hence, from a given plant installation. Precipitation is thought to occur better at lower concentrations, but use of low precipitation concentrations while digesting at high concentrations requires dilution and additional operating costs for subsequent evaporation. Choosing digester conditions involves balancing these physical factors with local economics, together with the designer's experience. This has resulted in the spectrum of operating conditions given in Table 6.

The conditions listed in the first line of Table 6 are those for digesting bauxite at the atmospheric boiling point. Quite high alkali concentrations are required and the evaporation requirement is an extraordinary 5.3 t of water for a tonne of Al_2O_3. Most plants digesting gibbsitic bauxite use the conditions on the second line of Table 6. Boehmitic bauxite is digested using one of two general sets of conditions. The first is European practice, in which higher concentrations and dilution prior to precipitation are preferred to higher digest temperatures. When American companies began processing boehmitic bauxite from the Caribbean area, most chose the same concentrations used for gibbsitic bauxite; therefore, a higher temperature was required.

The second important reaction in digestion is *desilication.* In the equation below, kaolinite is used to illustrate the reaction of siliceous minerals with the process solution:

$$Al_2O_3 \cdot 2\,SiO_2 \cdot 2\,H_2O + 6\,NaOH$$
$$\rightarrow 2\,NaAlO_2 + 2\,Na_2SiO_3 + 5\,H_2O$$

The soluble products react to form a series of precipitates with zeolite structure, having a composition of approximately $Na_8Al_6Si_6O_{24}(OH)_2$.

Depending on temperature and concentration, the ratio of $Al_2O_3 : \times SiO_2$ in the zeolite (tectosilicate) structure can vary. For each Al^{3+} replacing Si^{4+} in the lattice, one Na^+ is taken up to maintain charge neutrality. Anions, such as SO_4^{2-} or CO_3^{2-} may substitute for OH^- in the structure. The formation of the zeolitic desilica-

Table 6. Commercial digestion conditions

Bauxite type	Temperature, K	c_{NaOH}, g/L	Final $c_{Al_2O_3}$, g/L
gibbsitic	380	260	165
	415	105 – 145	90 – 130
boehmitic	470	150 – 250	120 – 160
	510	105 – 145	90 – 130
diaspore *	535	150 – 250	100 – 150

* CaO is added to digests to accelerate dissolution of diaspore.

tion product (DSP) therefore leads to costly loss of sodium hydroxide. This reaction, however, is necessary for lowering the level of dissolved SiO_2 to less than 0.6 g/L, the maximum acceptable concentration.

The rate-determining step in the desilication reaction is the nucleation and crystallization of the desilication product. Therefore, the presence of seed particles is important; without seeds, solutions containing 0.75 g/L SiO_2 will not react in 40 min at 415 K. This has led to the paradoxical situation that some bauxites contain too little reactive SiO_2 for good desilication. The slurry blending and storage operation discussed earlier can be an important part of the desilication process. If the storage temperature is above 355 K, about 80 % of the reaction takes place in 8 h. More important, seed is formed so the desilication reaction in the digest is not delayed. Very low SiO_2 concentrations can be achieved if an excess of CaO is charged. At high temperatures, and with the lime additions, a less soluble desilication compound (cancrinite) is formed. European plants use longer holding times during or after digestion to facilitate desilication.

Some CaO is added to the digest even when extreme desilication is not required. The calcium reacts with the carbonate and phosphate compounds as follows:

$$CaO + H_2O \rightarrow Ca(OH)_2$$

$$Ca(OH)_2 + Na_2CO_3 \rightarrow CaCO_3 + 2\,NaOH \text{ (causticization)}$$

$$5\,Ca(OH)_2 + 3\,Na_3PO_4 \rightarrow Ca_5(PO_4)_3OH + 9\,NaOH$$

The last reaction controls the level of phosphates in the process solution; this impurity can affect clarification adversely. Causticization in the digest was more important when prices were such that the sodium required by the process was supplied more cheaply as Na_2CO_3. Its current importance is in control of the CO_3^{2-} concentration, which, at high levels, can affect precipitation. In modern practice, the causticization reaction is carried out on dilute process solutions outside the digester. Maintaining low concentrations and having much of the NaOH combined as $NaAlO_2$ are favorable to more complete reaction of CO_3^{2-} with Ca^{2+}.

3.1.3. Equipment

The equipment for digestion includes the reactor vessel, heat-exchange equipment, and pumps. The first reactors were horizontal vessels with crude agitators mounted on axial shafts. These were filled with a slurry of bauxite, lime, and process solution. They were closed and heated individually by injecting high-pressure steam. At the end of the designated holding time, a discharge valve was opened and a slurry was forced into another vessel at atmospheric pressure. Only a small portion of the steam flashing from the slurry as the pressure was reduced could be recovered. Continuous operation was introduced in the 1930s in which heat could be exchanged between the hot stream leaving the digester and the cooler, incoming stream. This greatly reduces the energy requirements.

Reactors. Digester vessels, whether batch or continuous, provide intimate contact between the bauxite and the solution for a period long enough to complete the extraction and desilication processes. The equipment designed for this purpose is quite diverse. Agitated horizontal vessels have been replaced by vertical units to avoid the mechanical problems with sealing

Figure 9. High-temperature digestion and heat recovery

the agitator shaft. Both designs have used a series of vessels to minimize short circuiting of the flow. European practice includes use of a series of vertical agitated vessels, each operating at a higher temperature than the preceding one. These units are heated by flashed steam in internal steam coils. A German digester design uses concentric pipes; the liquid being heated flows through the inner pipe while the hot slurry from the digester is returned through the outer pipe. This tube digester has been modified by placing several tubes for the cold slurry in parallel inside a larger outer tube. This reduces the length of the unit. The variety of digester design is illustrated in Figures 9, 10. The flow through single-digester units may be as high as 12 m^3/min.

Figure 10. Tube digester
a) Piston pump; b) Heat; c) Condensate; d) Flow control valve; e) Steam

The usual *construction material* for digesters is mild (low-carbon) steel, despite data showing that, at the temperatures and NaOH concentrations involved, there may be stress corrosion cracking resulting from alkali embrittlement. The presence of the $[Al(OH)_4]^-$ ions reduces the activity of OH^- in the solution. Finely divided Fe_2O_3 in the bauxite quickly saturates the solution with Fe^{3+}, suppressing corrosion of the metal. Some digestion equipment has been nickel plated for safety.

Flashing. In most plants the hot slurry from the digester is flashed in a series of pressure vessels until it reaches the atmospheric boiling point. The steam generated in flashing is used in heat exchangers to heat the flow of liquor and bauxite coming to the digester. Flashing also removes water from the process stream, thereby accomplishing a significant portion of the evaporation needed. Normally, heaters are tubular, but coils of tubing also are used. As few as three stages of flashing may be needed when the digestion temperature is 418 K, and this may be increased to ten stages for a unit operated at 515 K. Figure 9 is a schematic diagram of a high-temperature digestion unit.

Heat Exchangers. Operating practice has been divided as to whether the bauxite slurry should be heated separately or whether it should be mixed with the rest of the solution and then heated. These two modes of operation have been designated the single- and the double-stream processes. Those favoring separate heating of the bauxite slurry, the double-stream option, feared rapid deposition of desilication product on the heat-transfer surfaces. Experience has shown that, particularly if the bauxite slurry is

stored for blending, those fears are unfounded. The rate of fouling is no higher than for heating clean liquor. In both options there is slow deposition of desilication product on the heat-exchanger surface because the desilication reaction does not reach equilibrium in the digester and continues at a slow rate wherever the solution temperature is raised. The encrustation must be removed periodically by washing with dilute HCl or H_2SO_4, or by mechanical means to maintain a high heat-transfer rate.

In some plants using the double-stream system, the bauxite slurry is heated in contact heaters. These heaters are designed much like barometric condensers. The liquid is forced to fall through the steam in the heater in droplets or in thin films. The large surface area exposed results in high heat-transfer rates, and because there is no metallic surface, there is no fouling. The penalty is higher dilution.

The heat needed to raise the temperature above that achieved in the flashing system can be introduced by direct injection of steam. More often the final heating to the digest temperature is done in a separate heat exchanger, with the energy coming from steam, hot oil, or molten salts.

Pumps. *Centrifugal pumps* are used in most digester systems. Those used for pumping slurries are built of wear-resistant alloys. A great deal of maintenance is required to keep the shaft seals operating well. In some plants, concern about pump wear has led to the use of *diaphragm pumps.* In such pumps a check valve admits the slurry to a chamber on one side of a flexible diaphragm. When that chamber is full, oil at high pressure is forced into a chamber on the other side of the diaphragm. This moves the slurry through another check valve into the digester. Therefore, no rapidly moving parts are in contact with the slurry. In a Japanese modification, called the *Hydrohoist,* the diaphragm is replaced by a sphere that is free to move the length of a cylinder. Slurry is kept in one end of the cylinder and the drive fluid, which is clean process solution, is in the other end. Because of this choice of drive fluid, leakage past the sphere is of no consequence and tight clearances are not required.

Measurement and Control. Operating variables that must be controlled are temperature, solution concentration, and degree of desilication. The holding time is fixed by the design of the digester vessels. As noncondensable gases are formed by the reaction of the solution with organic materials in the digest, it is necessary to vent these gases so that the digester remains full. Venting can be controlled by sensing the liquid level with a float or a radioactive sensor. Temperature measurement and control are relatively simple because only the temperature from the final heater is critical. Concentration control comes from blending the bauxite and careful proportioning of the slurry and clean solution flows. Originally, feedforward control was used in which the composition of the incoming materials was used to set the rates at which they were added. In modern practice feedback control is based on the composition of the exiting solution. Chemical analyses of the solution can be used, but the time lag involved makes this control imprecise. Nearly real-time control has been achieved by using the fact that the conductivity of the solution at a given temperature is a linear function of the mass ratio of Al_2O_3 and NaOH. This is the variable of interest. In modern plants the output of the sensor goes to a computer, which in turn controls the amount of bauxite slurry pumped. Such control has reduced the variance in concentrations to about a third of the values experienced earlier. This permits operation closer to the maximum safe concentration with less risk of premature precipitation of Al_2O_3 in clarification.

3.1.4. Residue Separation

The next step in the process is the separation of bauxite residue solids from the solution. A wide variety of equipment and procedures is used in this operation. The methods chosen depend on the quantity and properties of the residue.

The particle size distribution of the residue solids is usually bimodal. The coarse fraction over 100 µm in diameter is termed *sand*, whereas the rest of the solids are finer than 10 µm. The sand fraction may range from 5 to nearly 50 % of the total. The lowest amounts are in the Caribbean bauxites and the highest are in the residue from Western Australian bauxite. In the plant the sand fraction is separated from the process stream in liquid – solids cyclones or in more

primitive settling devices. A variety of equipment, including Dorr, Hardinge, and Aikens classifiers, have been used to wash the sand free of process solution before it is discarded. In all of these units the sand moves countercurrently to the wash water so that a maximum of washing is done with a minimum of water. The wash solution is added to the balance of the process flow and proceeds to further clarification steps for removal of the fine solids.

In most plants the fine residue fraction is settled in raking *thickeners* of the type illustrated in Figure 11. These vessels may exceed 49 m in diameter. Some older plants used multideck thickeners. Difficulties in keeping the multideck units in balanced operation have led to almost exclusive use of single-deck units in new construction.

The desanded slurry is fed at the center of the thickener and clarified solution overflows at the perimeter. As the solution flows radially across the thickener, both the horizontal and vertical velocities become very low. The solids, having a higher specific gravity than the solution, sink to the bottom of the thickener. A settling rate of 1.5 m/h is sufficient for commercial operation. The solution overflowing the thickener usually contains less than 0.3 g/L solids, whereas the underflow ranges from 15 to 35 wt % solids. The rotating mechanism has plows mounted at an angle to the arm. These slowly move the settled pulp across the bottom of the thickener to a discharge port. A few units have been designed with the discharge at the perimeter rather than at the center. The objective was to avoid the need to elevate the units to provide access to a center discharge.

The fine solids behave as a relatively stable colloidal suspension, so they settle slowly if not treated further. The addition of *flocculants* improves the clarity of the thickener overflow, the settling rate of the solids, and the solids content of the underflow pulp. Flocculants act by binding the very fine particles into flocs that may be several millimeters in diameter. The ratio of mass to drag forces is increased so the flocs settle more rapidly.

Starch from grains or roots was the first flocculant; the dosage varied from 0.5 to 3 kg per tonne of bauxite. The amount required increases as the surface of the residue increases and is affected by the mineral composition of the residue. Starch has the advantages of being inexpensive and ubiquitous. It does react with the NaOH in the solution to add organic compounds to the solution. In the 1950s water-dispersible polymers were proposed as flocculants. The first compounds were effective when added at 10 % of the starch charge, but they were expensive so they offered no economic advantage. More recently, flocculants based on acrylate – acrylamide copolymers have begun to replace starch. The functional groups of these anionic flocculants can be modified to suit specific operating conditions. Different materials may be used in the thickeners and in the washing operation. In some cases a small amount of starch is added to the synthetic flocculant to improve overflow clarity. These synthetic materials

now offer an economic advantage because they have been made less expensive and more effective.

With the residue concentrated in the thickener underflow, the next task is to *wash* it free of process solution so that it can be discarded. This is usually done in countercurrent decantation systems using washing thickeners that are similar in design to those used for settling. The washing operation is done in as many as seven stages with the solids moving countercurrent to the wash stream. This is illustrated in Figure 12. An equation can be written for each stage expressing a material balance between soluble materials and dilution. Computer models of the washing system allow accurate prediction of performance.

Figure 12. Flows at stage *n* in countercurrent decantation (O = overflow; U = underflow)

In *residue washing,* the objective is to minimize both the value of the soluble salts lost and the cost of evaporating the added wash water. The solubles in the discarded pulp can be reduced by increasing the solids content of the underflow. This reduces the amount of solubles carried from one stage to the next so that dilution is more effective and can be accomplished by using more flocculant or by increasing the holding time in the thickener. There is some risk in the latter change. If some undissolved gibbsite or boehmite remains in the residue, it may induce precipitation with a resulting loss of Al_2O3.

In some plants vacuum drum-type washing filters are used to replace some or all of the washing thickener stages. The solids content of the residue may be increased to 50 – 60 wt % by filtration. Therefore, only about 33 % as much solution is needed compared to plants using thickeners and this results in a great increase in the effectiveness of washing. Calculations for countercurrent washing show that two stages discharging at 55 % solids are more effective than six stages operating at 20 % solids.

Another approach only recently introduced into plant practice is called the deep thickener. This equipment was developed in the British coal industry to concentrate the slimes from coal washing. In the deep thickener, increased quantities of flocculant are used, and a column of residue pulp up to 10 m deep is maintained. The hydraulic pressure of the deep column appears to densify the pulp so that underflow solids approaching the concentration of filter cake are obtained. The overflow from these units contains more solids than the flow from standard thickeners, but the units are finding use in concentrating residue for washing and for disposal. The simplicity of the equipment adds to its appeal.

The final stage of clarification is *polish filtration* of the solution, sometimes called clear pressing. Most of the residue solids have been removed from the process solution in the previous steps, but product purity must be protected by removing the few particles of solids remaining. Filter presses are used most widely.

Another approach to polish filtration is use of a stationary filter in which the medium is uniform, fine sand a meter deep. Gravity provides the force to move the solution through the sand bed. During operation, the fine solids are mixed with the sand, from which they are elutriated at the end of the cycle. Such filters can be automated and are especially effective with residues that are difficult to process.

Close attention is required to keep the solids content of the filtrate down to 0.5 mg/L to protect product purity. Light transmission of the filtrate is used as an index of clarity. Purity originally was determined visually, but nephelometers are used now. If evidence of solids is found, the filtrate from each filter is scanned to locate the source. Some solids may pass through the filter cloth before a layer of solids forms to serve as a barrier, so it is common practice to recycle the first portion of filtrate.

Control in clarification has two major objectives; the solids must be removed and the washed residue must be prepared for discard, using a minimum of wash water. The first objective is achieved by measuring the cloudiness of the filtrate. High solids in the underflow are dependent in part on the retention time in the thickener, so measurements must be made of the pulp level in

the unit. Automatic determination of the interface between clarified liquid and pulp has been done by ultrasonic and by optical scanning. The density of the underflow pulp is monitored by a device that measures absorption of radiation or by gravimetric measurement. If the pulp is too dilute the rate of withdrawal is decreased. This control can be overridden if the pulp level in the unit rises too high so that there is concern that the solids in the filter feed may become excessive. The flows of solids and wash water also must be measured and proportioned for efficient operation.

3.1.5. Precipitation

The filtered solution has a temperature of 375 K and it must be cooled to 335 – 345 K before precipitation. This *cooling* is usually done in a flashing system analogous to that used in recovering heat in digestion. Because the temperatures are below the atmospheric boiling point, the flash vessels and the heat exchangers must operate under vacuum. Most of the heat removed by flashing is transferred to the colder solution returning from precipitation. Plate-type liquid – liquid heat exchangers have also been used. The solution can be cooled further midway through the precipitation operation. This allows higher recovery of Al_2O_3 without using conditions that lead to excessive nucleation of product.

Recovery of the $Al(OH)_3$ from the process solution is known as precipitation, decomposition, or Ausrührung. The reaction is the reverse of the digester reaction given earlier. The cooling done after digestion and filtration has moved the solution into an area of the solubility diagram known as the metastable region. The concentration and temperature are such that the solution is supersaturated with $Al(OH)_3$ but is not saturated enough for spontaneous crystallization. This is illustrated by Figure 13. At the digest temperature, T_1, the Al_2O_3 concentration is increased to point P on the diagram. Cooling to temperature T_2 results in crossing the solubility curve into the metastable region. Addition of $Al(OH)_3$ seed at this point causes precipitation and the concentration of Al_2O_3 approaches the solubility curve at T_2. The additional cooling recently adopted moves the solution conditions further to the left in the diagram above a lower point on the solubility curve.

Figure 13. Generalized solubility curve

The *kinetics* of the precipitation reaction are represented by the equation:

$$\frac{-\mathrm{d}c}{\mathrm{d}t} = k\exp\left(-E/RT\right) A\left(c-c_\infty\right)^2$$

where:

c = Al_2O_3 concentration, g/L
k = constant
E = activation energy, about 59000 J/mol
R = 8.31441 J mol^{-1} K^{-1}
T = temperature, K
A = seed area, m^2/L
c_∞ = concentration at equilibrium

The reaction is second order, i.e., the rate is affected by the square of the difference between the actual Al_2O_3 concentration and the equilibrium concentration. The operating temperature affects the equilibrium concentration and the reaction rate. Because seed area is important, the seed charge must be as high as can be maintained while meeting other operating objectives.

The first objective in precipitation is to produce $Al(OH)_3$ that, when calcined, meets the specifications for metallurgical alumina. These specifications are discussed in Section 5.2. The second objective is to obtain a high yield from each volume of solution. This increases the plant capacity and reduces the amount of energy spent in heating and pumping the solution. At the same time, the processes serving to create new $Al(OH)_3$ particles must be controlled so that the

number of seed particles created equals the number of particles leaving the system as product. This requires balancing nucleation, agglomeration, growth, and particle breakage, so a combination of science and art has developed.

About 2×10^{10} nuclei must be formed in each liter of solution to balance the process. The rate of *nucleation* is a strong function of both the degree of supersaturation and of temperature. Very few nuclei are formed if the temperature is above 350 K. A change in the operating temperature of only 5 K will change a system from a net producer to a net consumer of nuclei. Temperature changes of 2 – 3 K are the most frequently used control measures.

The nuclei *grow* by accumulation of $Al(OH)_3$ on their surface if they become large enough to be viable seeds. The rate of growth can be as high as 9 µm/h, but it is generally much lower. The growth rate is independent of the particle diameter. Particles also increase in size by *agglomeration.* By a process that is not well understood, the nuclei form clusters in the first few hours of the cycle in batch precipitation. When the supersaturation is low, this agglomeration does not occur. Some speculate that when the rate of precipitation is high, the $Al(OH)_3$ is not well crystallized when it is first deposited on the seed. This later may serve as the bond for agglomeration. At low supersaturation the deposited material is better ordered. The action of mechanical equipment in precipitation can *break* fragments off crystals or break up agglomerates, creating secondary nuclei, but this is not a major factor in most plants.

Figure 14. Technical aluminum hydroxide (gibbsite)

Figure 14 is an electron micrograph of some $Al(OH)_3$ produced in a plant operation. The particles are obviously the result of agglomeration. Those agglomerates having fewer particles can be shown by thin-section micrographs to have grown radially from an agglomerate of relatively few nuclei.

In Figure 15, the Al_2O_3 concentrations in experimental precipitations is shown as a function of time and temperature. The slopes of these curves indicate the rates at which precipitation is progressing. All curves show a high rate at the start and appear to be approaching a final value asymptotically. The final concentrations were well above the saturation level, but in these as in plant operation the rate became unusually low, so the process was terminated.

Precipitators are vertical cylinders; the height, which may be 30 m, is usually 2.5 – 3.0 times the diameter. The seeded slurry is circulated to maintain intimate contact between solids and solution. Early precipitators circulated the material by means of a central air lift pipe. Air introduced at the bottom of the pipe reduced the apparent density of the slurry within the pipe. This caused slurry to flow into the bottom of the pipe to establish circulation. Modern precipitators are circulated mechanically by impellers up to 3 m in diameter operating in a draft tube. In these units the flow is downward through the tube, so the tank bottoms are nearly flat to reverse the flow and cause upward motion of the slurry. Tanks with air lifts have conical bottoms to direct the flow to the central air lift.

Originally, precipitators were filled individually in *batch operation.* This method had several disadvantages, chief of which was the need for many operators because the operating cycle of a single precipitator required at least 15 separate operations. Control was difficult and batch operation left equipment out of service part of the time.

Nearly all plants built in the last 30 years have used the *continuous system.* Up to 13 tanks are placed in series so that the flow of seed and solution moves by gravity through channels connecting the tank tops. Continuous flows are much easier to measure and to automate. The number of flows is reduced, so control is better and the labor requirement is reduced. There are some operating problems. One is to avoid passage of the slurry across the tank tops, thereby reducing the retention time. Movement of solids from tank to tank is also a problem. An ideal system

Figure 15. Effect of temperature on precipitation

Figure 16. Al_2O_3 concentration profiles in batch and continuous precipitation

would retain fine particles in the tanks and move only the coarse material to the discharge. This is not possible, so a compromise method of operation must be found. Precipitation takes place at constant conditions in each tank instead of following a continuous curve, as in Figure 16. This tends to decrease production per tank, but the loss is more than recovered because the tanks are always in use.

Several patterns have been used to supply the *seed for precipitation.* The earliest was to neutralize a portion of the solution. An $Al(OH)_3$ gel was precipitated that changed into fine crystallites on aging. This very fine material was grown through at least one cycle to provide an active seed for product precipitation. The more common approach is to use fine particles, produced in the operation, as seed. The slurry leaving precipitation is classified into a coarse product fraction and one or more fine fractions. The fines are returned to the process to grow to product size. Classification is done by controlling the flow rate through tanks so that the fines are elutriated. Liquid – solid cyclones are coming into use because they provide more accurate separations. The seeding and classification systems have become increasingly complex. In modern plants at least three fractions are separated. In some plants the agglomerates formed from fine seed must pass through the system once more before becoming product. This reflects the belief that the agglomerates must be made tougher by deposition of additional $Al(OH)_3$ so that they do not disintegrate in calcination and subsequent handling.

In a modification [47], a relatively small charge of fine seed is added to the first tank in a series. This promotes agglomeration. Then, additional coarser seed is added to the second or third tank to provide the large seed area needed for high production. As indicated previously, cooling may be done between units in a series to increase the supersaturation in the final tanks, thereby increasing the production rate. A further change in modern plants is to filter the seed slurry being recycled. This decreases the amount of spent solution returning to the system and increases both the Al_2O_3 concentration in the first tank of the series and the overall production.

The control variables available to the precipitation operator are the temperatures in the system; the flow per unit, which translates into holding time; the amount of seed; and the particle size of the seed. Some of these variables are difficult to control, so the system usually cycles slowly from coarser than desired to finer. There is enough inventory in the process so that minor cycles can be tolerated without affecting plant output.

3.1.6. Impurities

The impurities in the product Al_2O_3 are affected by all of the foregoing operations, including selection of the bauxite. There are at least three classes of impurities. The first is residue solids that are not removed in clarification. The large surface area of $Al(OH)_3$ in precipitation effectively sweeps up these solids into the product. The preventive measure is increased vigilance in filter maintenance and operating. The second class is materials that are in true solution, such as sodium and gallium. The third group includes materials that are in solute form at the temperature of digestion but precipitate later in the process. Their solubilities may be only milligrams per liter and return of the solution to equilibrium at lower temperature may be slow. If precipitation is not completed before filtration, the remaining impurities appear in the product. There are also other impurities that do not fall neatly into these categories.

Sodium is the main component of the process solution and is also the largest contaminant of the product. The Na_2O content of alumina can be decreased by increasing the seed charge and by increasing the precipitation temperatures. The real variable that these operating changes help control is the rate of crystal growth. Higher temperatures, greater seed area, and lower Al_2O_3 concentrations all slow growth and give impurities more time to diffuse from the surface. By proper control of these variables an order of magnitude decrease in the Na_2O content of a commercial product has been achieved. Some sodium is lost in the Hall – Héroult cells during smelting by absorption into the cell lining and by conversion to sodium metal, so complete absence of sodium in metallurgical alumina is not necessary. The target is to balance the input to the cells with the losses. This requires Al_2O_2 containing about 0.4 – 0.5 wt % Na_2O.

Gallium is a ubiquitous component of aluminous ores. Its chemistry is similar to that of aluminum, so it accumulates in Bayer process solutions until an equilibrium is reached at about 0.2 g/L. The gallium content of Al_2O_3 is a linear function of the gallium concentration in the solution. Therefore, the amount leaving in the product equals the input. Because gallium is in true solution, the same changes that lower the Na_2O content of the product lower the gallium content. Only in the production of high-purity metal has there been concern about the gallium content of alumina. About 10 t/a of gallium is recovered from Bayer process solutions. This is the best source for the production of gallium (→ Gallium and Gallium Compounds).

Silicon is a component of many aluminum alloys, yet the specification for Al_2O_3 is less than 0.02 % SiO_2. This value is only 25 % of that specified 50 years ago. The SiO_2 is in solution, but it appears to be added to the product through a slow continuation of the desilication reaction (Section 3.1.2). There is also evidence that if the rate of Al_2O_3 deposition on seed is not high, the seed surface becomes at least partially covered with desilication product, thereby becoming less active as a seed for $Al(OH)_3$ precipitation and more active toward SiO_2. This impurity is controlled by driving the desilication reaction nearer to completion. Lowering the SiO_2 concentration of the solution below 0.1 g/L gives a product containing less than 0.003 % SiO_2.

Potassium is undesirable in the Al_2O_3 because it may destroy the graphite in Hall – Héroult cells by intercalation, i.e., it diffuses between the layers of the graphite structure, thus expanding its volume. Although it is soluble in Bayer solutions, there has not been a recorded instance of K_2O concentrations becoming high enough to affect the Al_2O_3 quality.

Iron(III)oxide (Fe_2O_3) as an impurity in Al_2O_3 has been the subject of much investigation. It is soluble up to ≈ 0.1 g/L in the solutions at digest temperatures (400 – 500 K), but only to ≈ 0.001 g/L at 333 K [48]. This reconciles the observations that Fe_2O_3 behaved at times as if it were in solution and as a colloid at others. There are several iron minerals that can serve as sources for the impurity. Hematite (α-Fe_2O_3) and goethite (α-FeO(OH)) are present in most bauxites. Goethite is slowly converted to hematite in high-temperature digests, particularly if CaO is present. This conversion improves clarification because hematite settles better than goethite. The mineral siderite ($FeCO_3$) present in some bauxites not only is a source of iron but also reacts with NaOH to increase the amount of causticization needed. Pyrite (FeS_2) is almost insoluble in Bayer solutions; its adverse effects occur when the sulfur is oxidized to sulfate in the presence of air and water. The sulfate will

react with NaOH to form Na_2SO_4 which has to be removed periodically.

Paradoxically, there is less difficulty with Fe_2O_3 as an impurity in processing bauxites containing a large amount of iron oxides. This is probably because the iron oxides serve as seed and hasten hydrolysis of the $NaFeO_2$ formed in the digest. Running the solution over iron oxide particles before filtration has been effective in controlling this impurity. Another process for lowering the iron content of Al_2O_3 is termed step precipitation. The filtered Bayer solution is lightly seeded with $Al(OH)_3$ for a short time to precipitate up to 3 g/L Al_2O_3. The seed and the small amount of precipitation effectively sweep the colloidal iron hydroxide particles from the solution, leaving an Fe_2O_3 concentration of less than 0.005 g/L.

Calcium also is a common impurity. The presence of increasing amounts of Na_2CO_3 in the Bayer solution seems to increase the CaO in the product. The calcium content of alumina, as with sodium, needs to be controlled such that the Hall – Héroult cell bath can come to an equilibrium level acceptable for cell performance. Calcium can be controlled by step precipitation or by lowering the carbonate content of the solution.

Lithium is also acceptable in Hall – Héroult cells. It can be removed by step precipitation.

Other metallic impurities that appear in many bauxites in small amounts are chromium, copper, manganese, titanium, vanadium, and zinc. Generally, these impurities are not so concentrated that removal processes are required. Sulfide salts have been added to precipitate copper and zinc. The chromium is a problem only if it is oxidized; the organic salts in the solution are usually a sufficient reductant. The addition of manganese compounds as oxidants for organic material has been reported.

Anions, such as carbonate, chloride, fluoride, and sulfate, are known to interfere with $Al(OH)_3$ precipitation. The carbonate ion is controlled by addition of lime, although processes have been reported in which Na_2CO_3 is removed by evaporative crystallization or by cooling the solution to 260 K. The sulfate and chloride ions usually are controlled naturally, as their salts are incorporated in the desilication product in sufficient quantities to maintain an equilibrium. There are commercial operations in which the sulfate salt is removed by evaporation and crystallization. The least soluble salt is schairerite ($Na_2SO_4 \cdot NaF$), and when the fluoride ion is depleted, burkeite ($2Na_2SO_4 \cdot Na_2CO_3$) appears. The fluoride ion is almost never present in quantities large enough to be harmful.

Many bauxites contain *phosphate minerals*. Apatite ($3Ca_2P_2O_8 \cdot CaF_2$) does not react in the process; indeed, this compound or its hydroxy counterpart is formed when soluble phosphates react with calcium in the digest. Aluminum phosphates, such as wavellite ($4AlPO_4 \cdot Al(OH)_3 \cdot 9H_2O$) do react, forming Na_3PO_4 as the soluble phosphate. The phosphate ion interferes with flocculation of bauxite residues containing goethite, probably by competing for attachment sites [49]. The concentration of phosphates never is high enough to interfere with Al_2O_3 purity. Addition of CaO to the digest is the control measure.

Organic matter in bauxite, whether it be roots and twigs from plants or humic acids from decayed matter, reacts in the digest to form a wide variety of organic compounds. Some operation process streams have exceeded 15 g/L organic carbon in solution. There is evidence that larger molecules are oxidized in the process all the way to Na_2CO_3 and sodium oxalate ($Na_2C_2O_4$). In addition some, but not all, of the organic compounds may interfere with precipitation [4].

The effect of sodium oxalate on processing has not been quantitatively determined, yet many plants incorporate equipment for crystallization of the oxalate salt from the solution. Others wash this salt from the $Al(OH)_3$ seed and recover it from the wash water. The evidence is overwhelming that operations are improved by the oxalate removal techniques. Early removal processes included evaporation to high concentrations followed by centrifugal separation of the gelatinous salt mass. In other plants, a portion of the solution was mixed with bauxite or $Al(OH)_3$ and heated to 1280 K. This destroyed the organic compounds and formed $NaAlO_2$, which could be recovered in the process. A German process adds magnesium salts to the digest to remove the deleterious organic compounds. Still others are investigating methods of oxidizing the organic material in the solution [50].

3.1.7. Calcination

The final operation in production of alumina is calcination. The temperature of the $Al(OH)_3$ is raised above 1380 K resulting in the reaction:

$$2\,Al(OH)_3 \rightarrow Al_2O_3 + 3\,H_2O$$

As discussed in Section 2.2, this reaction can take several pathways and several transition forms may appear. The end of all pathways is α-alumina. In older European practice, a major portion of the alumina was converted to the α-phase, sometimes by the addition of a fluoride salt to lower the temperature of transformation. In American practice, calcination always has been less severe; so, normally, $\leqq 20$ % of the alumina is in the α-phase.

Before calcination, it is necessary to *wash* the process solution from the coarse $Al(OH)_3$. This is done countercurrently, using storage tanks and filters. As in residue washing, increasing the number of washing stages and the concentration of solids leaving each stage improves the effectiveness of washing. Vacuum filters of several designs have been used for the final separation. The early Oliver and Dorr drum filters have been replaced by horizontal rotary filters because better washing can be achieved. The quality of the wash water is of some concern because such impurities as calcium and magnesium can be adsorbed on the surface of the $Al(OH)_3$.

Earlier, calcination was done in reverberatory furnaces. These had neither the capacity nor the thermal efficiency required, so they were soon replaced by *rotary kilns.* These kilns are cylinders that may be 3.5 m in diameter and over 80 m long. They are mounted on bearings and rotate about an axis inclined at a small angle to the horizontal. Damp $Al(OH)_3$ from the filters enters the upper end and slowly tumbles toward the lower end, traveling against a stream of hot gas formed by combustion of natural gas or oil at the discharge end. Early kilns were less than 40 m long, but longer units have better thermal efficiency and higher capacity.

Product coolers were added to kilns so that part of the heat in the incandescent product could be transferred to the combustion air. Early coolers followed designs developed in the cement industry and were themselves rotary units much like, although smaller than, the kilns. Improved coolers fluidize the product Al_2O_3 around heat-exchange surfaces, often in several stages. In such coolers, the heat can be recovered in combustion air or in wash water and the product can be cooled readily to 425 K.

The progressive adoption of large-capacity *stationary calciners* has reduced fuel consumption for alumina calcination to ca. 3.1 GJ per tonne of alumina, which compares to ca. 4.5 GJ per tonne for earlier rotary kilns. Several stationary calciner designs with capacities of > 2500 t/d alumina are now commercially available. In stationary calciners, a combination of fluid beds and stages in which the solids are transported in suspension is used. Figure 17 is a schematic diagram of a commercial unit capable of calcining 1500 t/d.

The $Al(OH)_3$ is washed and dewatered on the filter (a) and is conveyed into the flash dryer (b), where it encounters hot gas from cyclone (g). The gas evaporates the free water from the particle surfaces. Because the temperature exceeds 480 K, a portion of the water of hydration also is driven from the crystals. Cyclone (c) separates the solids from the gas. The gas, cooled almost to its dew point, leaves the unit through the electrostatic precipitator (j), where dust is recovered. Vessel (d) serves as a surge buffer to smooth the flow of solids through the unit. The solids are separated in cyclone (g) to enter the vessel (f) where combustion of fuel is taking place. Vessel (e) allows a holding time at the calcination temperature so that the water content of the product is low. A small amount of fuel can be burned in this vessel if a higher temperature is desired. In this design the flow of solids is counter to the flow of the gas.

The solids are cooled, also in counterflow, by the combustion air in unit (h). Final cooling is in a fluidized bed unit (i). In the fluidized unit a small amount of air is introduced through a membrane at the bottom. This lifts but does not entrain the solids, so they behave much like a fluid. Heat is transferred at a high rate to air or water flowing through tubes submerged in the bed. The product Al_2O_3 can be cooled below 400 K with all of the recovered energy being used in the process.

The great advantage of the stationary units is that the heat required for calcination is 3100 MJ/t. The capital costs are lower than for rotary kilns of equal capacity, and the mainte-

Figure 17. Alcoa flash calciner

nance costs are lower primarily because the refractories are not subjected to rotational stresses. Because the capacity per unit is high and automation is quite easy, the labor requirements are low. The stationary units are being installed in retrofitting older plants as well as in new construction.

Alumina calcined in stationary kilns has a lower α-alumina content and a higher surface area than alumina calcined at the same temperature in a rotary kiln. This reflects the shorter residence time and the absence of a high-temperature flame in the static units. Photomicrographs show that the rapid temperature rise creates vapor pressure within the particles that tends to fracture large crystals.

The characteristics of the metallurgical alumina are controlled mostly by the time and temperature of calcination. The important parameter is the reaction between the $Al(OH)_3$ feed and the flow of fuel. The fuel must be free of impurities that can contaminate the alumina. Sulfur and vanadium in fuel oil are limited by concern for product purity. The amount of combustion air must be sufficient to burn the fuel completely without the use of a great excess that increases the gas flow and thereby reduces the thermal efficiency. Factors affecting fuel economy and alumina quality in modern stationary calciners are reviewed in [51].

3.1.8. Evaporation

As is shown on the flow sheet for the Bayer process (Fig. 7), the solution continuously cycles through the plant. Consequently, any wash water used must be evaporated so that the solution volume can be controlled. About 10 % of the flow is evaporated in the two cooling areas by being flashed into steam. In high-temperature digesters, the amount of flash evaporation is even larger. At least one plant processing high-grade bauxite was designed without any additional evaporation capacity. In most cases, the economics require installation and operation of evaporators. The objective is to minimize the summed costs of evaporation and the value of the soluble salts lost by incomplete washing. The minimum is usually attained with a net dilution of the residue of 1.5 – 2.0 kg/kg.

Table 7 lists the input and exit streams that compromise the dilution balance in an operating plant. Efficiency demands that all of these flows be monitored.

Table 7. Dilution balance

Inputs	Losses
residue wash	evaporation
sand wash	–
$Al(OH)_3$ wash	heat interchange flash
free moisture in bauxite	$Al(OH)_3$ to calcination
water in gibbsite and boehmite	free water with $Al(OH)_3$
injected steam	water with residue
purge water	vapor from solution surfaces
sodium hydroxide	
cleanup water (maintenance)	
uncontrolled dilutions	

Several evaporator designs are used in Bayer plants, but nearly all designs are used in *multiple-effect configurations.* In such units each stage operates at a lower pressure than the preceding one. Therefore, the vapor evaporated from the solution in the first stage is at a temperature high enough to heat the solution in the second stage, causing it to boil. This continues to the final stage, where the vapor is condensed. The condenser operates under vacuum so a jet pump is necessary to remove noncondensable gases from it. The more times the latent heat is used, i.e., the more stages that are present, the more water can be evaporated by the fuel steam used in the first effect. With Bayer solutions the maximum number of effects is six. This is because the boiling point of the solution is elevated 5 – 8 K by the dissolved solids. This reduces the steam temperature in each effect; with many effects there is little temperature difference available to cause evaporation.

An unconventional design called *continuous regenerative evaporators* has been used in some plants. These units are similar to the heating and flashing equipment used in digestion in that the feed is heated through up to ten stages without evaporation; the hot solution is then flashed through an equal number of stages and the steam is used for heating the feed. These units are not as efficient as most multiple-effect evaporators. The design choice is based on economics. Special evaporator designs may be used when it is necessary to crystallize organic or inorganic salts from the solution. In such designs pumps are used to increase the thermally induced flow through the tubes in the heaters. The heat-transfer surfaces in evaporators must be cleaned periodically to remove encrustations of desilication product and soluble salts.

Evaporators are controlled primarily by changing the amount of steam used. The flow of feed solution is regulated so that crystallization of soluble salts is either induced or avoided, depending on the operating mode. Temperature readings at each effect are compared to design values to indicate operating difficulties.

3.1.9. Residue Disposal

The most important environmental problem in the Bayer process is disposal of the bauxite residue. The solution left with the residue after an economical amount of washing is still very alkaline and cannot be allowed to contaminate ground water. Furthermore, the desilication product in the residue which is in contact with water has the capacity to exchange sodium for hydrogen. An aqueous slurry of the residue that had been washed with 1000 times its mass of distilled water still reached a pH value of 10.5 on standing. The undrained fine residue, even after years of consolidation, does not have enough strength to support buildings or equipment. These properties make disposal a difficult problem.

Previously, disposal was to a marine environment where the alkalinity was diluted by large quantities of water. This method has been used in the seas off Europe and Japan and in a river in the United States. Studies by environmentalists have indicated little damage to flora or fauna by the residue in a disposal area [52]. Today, however, environmental concern is so great that any new refinery is unlikely to be permitted to use marine disposal.

Early inland refineries simply dammed a convenient valley or built retaining dikes on flat land to form residue disposal areas. In some cases, the sandy portion of the residue was used to build the dikes. This method can be effective and cheap if care is taken to protect the surroundings by proper sealing techniques. The compacted residue has a lower permeability than many clays; yet, there have been isolated leaks into aquifers from such impoundments. Improved designs have been developed.

In Germany, retaining dikes are built with a portion of the structure designed to be porous. The dilute solution draining from the residue is channeled by the porous sections into water-

treatment facilities before being discarded. In some cases, the dike material exchanged ions with the solution so that little treatment was needed. The draining allowed consolidation of the residue so that it could support equipment. An American firm used a drained lake in which the bottom of the disposal area was covered with sand in which draining pipes were laid. The residue was pumped to these areas in the traditional manner as a dilute slurry. Most of the conveying water was decanted, while some percolated through the deposit to the drains. This design has two advantages: the residue consolidates better, so the storage capacity of an area is increased, and the hydraulic head on the bottom is reduced to zero, so that leakage is unlikely. Lakes have been built using the sand drains on top of seals of clay and plastic film for additional environmental safety.

Another modern disposal method, called *dry stacking*, takes advantage of the thixotropic nature of the residue. By some method, usually vacuum filtration, the residue is concentrated to 35 – 50 wt % solids. The slurry is agitated to reduce its viscosity by as much as two orders of magnitude and pumped to a disposal area. There it flows in lava-like fashion over the surface, establishing a slope away from the discharge point. In the absence of shear, the viscosity of the slurry increases and flow stops. Water does not separate from the slurry and the slope causes rain to run off rapidly, so the surface usually is losing water to the atmosphere. The surface becomes deeply fissured, further assisting drying. In about 90 days the residue may dry to 75 wt % solids, far drier than in any of the other disposal methods. In this state, it can support heavy earth-moving equipment and can be recovered or used for increasing the height of retaining dikes. This method maximizes the storage capacity of a given area and seems to pose the minimum threat to the environment. It does require construction of a permanent lake area for water storage and for cooling water. If any use is to be made of the residue, recovery is relatively easy.

Many investigations have been directed toward finding a commercial use for bauxite residue. The high iron content of some residues suggested production of pig iron. The quality of the iron was poor and the amount of slag formed exceeded the original amount of residue. Similarly, chemical processes have been developed for recovery of Al_2O_3, Na_2O, and TiO_2 from residue. Although all are technically possible, none has been feasible economically. Small quantities of residue have been used in making Portland cement, and smaller quantities have been used as a mold wash, as an insulating material, and, after reaction with H_2SO_4, as a water treatment. No chemical use is likely to consume a significant part of the residue [1], [5].

The residue is claylike and can be used in ceramic materials. The sodium causes formation of glasses at 1450 K, giving a vitreous bond. Bricks have been made commercially, but economic factors and other shortcomings of the brick have eliminated this use. Sintering the residue into aggregate for concrete may be economical where natural aggregate is not available.

In Texas, agronomists have shown that the residue can be used to neutralize acidic soil, replacing limestone. The cost of preparing the material for application and the logistics argue against extensive use. The conclusion is that large-scale use of bauxite residue is unlikely, so efforts should be directed toward reclamation of disposal areas.

3.1.10. Energy in the Process

Approximately 16 MJ are required to produce a kilogram of Al_2O_3. The worldwide range is 7.4 – 32.6 MJ/kg [48]. Variations in the quality of bauxite, plant design, and the size of the plants are the reasons for the large differences. Even with existing plants, large improvements in energy usage can be made. The Aluminum Association (USA) reports that the energy used per unit of alumina production in 1980 was 68 % of the energy used in 1972 [54]. The energy used in mining is less than 5 % of the total and is difficult to change. The energy for transporting bauxite is double that for mining it, because the average tonne of bauxite used in the United States is transported 4700 km. The situation worldwide is different because much of the bauxite is refined close to the mines.

Within the refinery, more than half of the energy is used for pumping and heating the solution and for evaporation. The previous discussion (Section 3.1.3) has shown that plant design can affect heat recovery and minimize en-

ergy use. Emphasis is being placed on increasing the amount of Al_2O_3 recovered from less than 50 g/L to over 65 g/L; some claim yields as high as 100 g/L. Because energy is more closely related to the flow of solution than to yield, the energy savings are large. The static calciners are nearly as efficient as they can be made because the temperatures of the gas and of the product leaving the units are very low. The change from rotary kilns has made up a large portion of the savings. There are still opportunities to improve operating practice and design to reduce energy consumption [55].

3.2. Economic Aspects

The largest cost elements in alumina production are raw materials, energy, and capital-related costs for the production equipment. Labor, operating supplies, and miscellaneous costs are much smaller than these three.

Bauxite is the most important raw material. Its cost includes those for mining, transport, levies, and taxes. In addition, the relative quality of the bauxite ore influences the expenditures for necessary reagents. Mining is relatively inexpensive because most deposits are covered with only a shallow overburden and can be mined with efficient equipment. Since the formation of the International Bauxite Association (IBA), levies and taxes have become a large part of the cost of bauxite. These costs have become relatively stable because most are related to the selling price of aluminum. The availability of bauxite from outside the IBA countries has allowed the effect of supply and demand to influence this cost. Where levies are not imposed, some system of taxation provides income to the producing nation. Transportation costs vary from very small to as much as half the delivered cost of the bauxite. Some bauxite travels less than 5 km by truck or conveyor belt to the refinery. Other bauxite may travel more than halfway around the world. The characteristics of bauxite most important in influencing its value are the available alumina and the reactive silica contents. The latter quantity has a great effect on the amount of sodium hydroxide and lime required in processing. Bonuses are given for high available alumina values, and penalties are charged for excessive silica.

In page 28, values were given showing the fourfold range in energy used to produce alumina. The most important variables are the plant design and the quality of the bauxite being processed. The most energy-efficient bauxites are gibbsitic, with very low residue content.

The capital costs also show wide variation. In 1990 U.S. dollars new installations may cost from $ 700 to $ 900 per annual tonne of capacity. The variables are design factors, location, capacity, and the properties of the bauxite to be processed. Much of the world capacity was constructed before construction costs were inflated and so has lower capital costs. The effect of capacity is also large, and plants producing 2×10^6 t/a have costs well below those of plants producing less than 10^5 t/a.

Alumina is traded on the world market as a commodity. Not all smelters have alumina capacity dedicated to them; they buy alumina on contract. Long-term contracts are common. In other instances, alumina is bought when needed at spot market prices. Since 1980, alumina has sold on the spot market for less than $ 150 to over $280 per tonne, reflecting a change in the relationship between supply and demand. Economics do not always control production because many corporations own refineries to supply their smelters. In other instances, national governments own a significant portion of a refinery and for political reasons may choose to operate in a noncompetitive situation. Costs per tonne of alumina can, under unfavorable conditions, exceed $ 200, although efficient plants may produce at roughly half this figure.

4. Other Processes for Alumina Production

4.1. Raw Materials

Many investigations have sought processes to replace the Bayer process by using raw materials other than bauxite [2]. Clay, primarily kaolinite, has been most considered because it can contain up to 39 % Al_2O_3 (→ Clays). Other materials, including anorthosite, nepheline, coal wastes, and fly ash, have been candidate raw materials. Yet, less than 2 % of the world supply of alumina is not made by the Bayer process. This happens

only where use of a domestic raw material and production of a desirable byproduct change the economic picture. Alumina from ores other than bauxite normally costs 1.5 – 2.5 times that from the Bayer process.

Because aluminum is amphoteric, both acid and alkaline processes have been developed. Most of the processes in each class follow the same general flow sheets.

4.2. Alkaline Processes

Sodium compounds, such as Na_2CO_3, react at 1280 K with the Al_2O_3 in aluminous ores to produce water-soluble $NaAlO_2$. This compound can be leached from the sinter with water and the solution treated to remove impurities; the purified solution is neutralized with CO_2 to recover $Al(OH)_3$. The last step regenerates the Na_2CO_3 for recycle. Difficulty arises because the aluminous ores contain SiO_2, which also reacts in the sinter to form soluble Na_2SiO_3. In processing, the desilication reaction discussed in Section 3.1.2 takes place, so the net recovery of Al_2O_3 is small or zero. If 2 mol of CaO, usually as limestone, is charged for every mole of SiO_2 in the raw material, insoluble calcium silicate compounds are formed. Under proper leaching conditions the $NaAlO_2$ can be recovered from such sinters with only slight loss.

The process has been used commercially in two American plants to recover most of the Na_2O and Al_2O_3 lost in the desilication product formed while treating high-silica native bauxite. A schematic flow sheet is given in Figure 18. The same process was investigated by the U.S. Bureau of Mines in a large pilot plant using anorthosite as the raw feed [51]. [Anorthosite is a mixture of the minerals anorthite ($CaAl_2SiO_8$) and albite ($NaAlSi_3O_8$).] Unless the composition, sintering, and leaching were closely controlled, the residue formed a gel in leaching and became very difficult to filter.

In a variation of the sintering approach, *calcium* replaces the sodium so that calcium aluminate ($3CaO \cdot Al_2O_3$) is formed as well as calcium silicate ($CaSiO_3$). The calcium aluminate reacts with Na_2CO_3 in an aqueous leach to form $NaAlO_2$.

$$3\,CaO \cdot Al_2O_3 + 3\,Na_2CO_3 + 2\,H_2O \rightarrow 2\,NaAlO_2 + 4\,NaOH + 3\,CaCO_3$$

Figure 18. Lime/soda sinter process flow sheet

In carbonation, $Al(OH)_3$ is formed and the Na_2CO_3 solution is regenerated. Nepheline, $(Na,K)AlSiO_4$, is treated by this process in the former Soviet Union. The calcium silicate residue is processed to make about 10 t of cement per tonne of alumina. The two products make the process viable here.

In the Pedersen process, sintering was replaced with a reducing fusion so that ferric ions in the ore were reduced to metal. Iron and the calcium slag were separated by decantation. During cooling, the $CaSiO_3$ passes through a crystalline phase change and the resulting stresses reduce the slag to powder [1], [2].

The sinter processes suffer economically for several reasons. The energy for sintering and for evaporation of the leach solution must be added to the energy required from operations analogous to those in Bayer processing. The capital investment is increased by the need for sintering equipment, and although limestone is inexpensive, the quantity required is so large that the expense is considerable.

4.3. Acid Processes

All of the acid processes follow the general flow sheet given in Figure 19. Usually the clay is prepared by grinding and roasting to about 1000 K. The roasting changes the kaolinite to meta-kaolin, from which the aluminum can be dissolved as the acid salt. The roasted clay is leached in an acid solution, usually at the atmospheric boiling point. Some investigators have chosen to leach at elevated temperature for processing advantages even though corrosion problems become more severe [1]. The siliceous residue is separated using sedimentation and filtration as in the Bayer process. Small amounts of iron salts remain in the clarified solution. These salts are removed by extraction with an organic compound that forms a complex with the iron but not with the aluminum salts. The organic solution is decanted from the aqueous phase and is treated to separate the iron salt and to regenerate the organic extractant.

Figure 19. Generalized acid process flow sheet

A hydrated aluminum salt is recovered from the aqueous solution, usually by evaporation and cooling to cause crystallization. In the *hydrogen chloride process,* advantage is taken of the low solubility of $AlCl_3$ in HCl. The HCl gas is absorbed in the solution both to regenerate the acid for leaching and to precipitate $AlCl_3 \cdot 6H_2O$. In all acid processes the hydrated salt is decomposed to Al_2O_3 by heating to 1300 K. Both water and the acid radical are driven off, and the acid is absorbed for recycling.

The U.S. Bureau of Mines sponsored a cooperative effort with several aluminum companies to investigate acid processes for recovery of alumina from clay [56]. For several reasons the HCl process was preferred: the reagent is inexpensive, processing conditions are not severe, and the salt can be recovered without evaporation. The HCl is not decomposed in calcination, and the water content of the acid salt is half that of other acid salts. Despite these features the process is not competitive economically with the Bayer process. A major fault is the amount of energy used to roast the clay, to evaporate the solution, and to decompose the acid salt. The investment is increased because of the corrosive solutions. A process disadvantage is that the Al_2O_3 is physically different from Bayer alumina, so smelting practice has to be changed for this aluminum source.

Pechiney and Alcan jointly operated a pilot plant using the H^+ *process,* a modification of the HCl process in which H_2SO_4 is added to the digest [52]. The combination of acids eliminated the need to roast the clay. Other processes use H_2SO_4, H_2SO_3, HNO_3, or NH_4HSO_4 as reagents to attack the clay, but no commercial use has been made of any of them.

Clay is a major impurity of coal, so the ash from coal may be considered an overroasted clay. The acid processes, with minor modifications, will extract alumina from ash [57]. Anorthosite that is high in anorthite reacts with boiling HCl; this approach has been investigated in Norway and Canada [58]. So far, all of these methods have served only to enrich the technical literature.

Two aluminous minerals that do not contain silica have attracted attention and, because of their composition, require different technology. Alunite, $K_2SO_4 \cdot Al_2(SO_4)_3 \cdot 2Al_2O_3 \cdot 6H_2O$ [*12588-67-9*], has been used commercially in

Russia. Both H_2SO_4 and K_2SO_4 are useful byproducts of alumina production by this method. The alunite is heated to drive off the hydrated water; additional heating under reducing conditions decomposes the aluminum sulfate without adversely affecting alumina recovery. The solid residue from the roast is a mixture of K_2SO_4, Al_2O_3, and gangue. The K_2SO_4 is dissolved in water and recovered. Alumina is extracted from the gangue in a modification of the Bayer process. In other approaches using alunite, the solutions are kept acidic so the alumina is recovered as a salt [59].

Dawsonite, $Na_2O \cdot Al_2O_3 \cdot 2\,CO_2 \cdot 2\,H_2O$ [*12011-76-6*], is found in some oil shales. The temperatures used to recover the oil from the shale decompose the dawsonite to $NaAlO_2$, which is soluble in dilute NaOH. The $Al(OH)_3$ and Na_2CO_3 can be recovered from the solution by carbonation. The economics are such that recovery of the oil must be competitive before mining and byproduct recovery can be considered.

5. Metallurgical Alumina

Aluminum production is the principal application for alumina; more than 92 % of world alumina production is used for this purpose. The property requirements for commercial metallurgical alumina are therefore of considerable importance to the alumina industry. Specifications have responded to changes in energy costs, aluminum cell design, cell gas scrubbing techniques, environmental regulations, working conditions in smelters, and the technology for alumina calcination. In general, there has been a shift away from relatively small-particle-size, highly calcined, "floury" alumina to a coarse, free flowing, dust-free, less calcined, "sandy" alumina of narrower particle sizing and higher chemical purity (→ Aluminum).

5.1. Alumina Properties Required for Smelting

Five developments have had a significant impact on alumina properties.

Cell Design. New, high current efficiency, prebaked anode cells with automatic center-feed systems require that the alumina be consistent, with trouble-free handling properties to insure proper conveying and volumetric metering from the feeder. These criteria are best met by a free-flowing, moderate- to low-calcined alumina with relatively coarse and narrow particle size distribution.

Cell Gas Dry Scrubbing. The use of dry scrubber systems employing cell-feed alumina as adsorbent for fluorides in effluent gas from the cells dictates other requirements for metallurgical alumina:

1) High adsorption capacity for hydrogen fluoride. This property is closely related to the specific surface area of the alumina, which is higher for the lower calcined aluminas.
2) Attrition resistance.
3) Free flowability.
4) Higher chemical purity to compensate for capture in the dry scrubber of impurities which are recycled to the cell.

Pot Room Working Conditions. Use of low-calcined, high surface area alumina as a cover for the cell bath reduces fluoride evolution within the pot room. Working conditions in the smelter are degraded by dust caused by fine particles of alumina. Reduction of the fines fraction ($< 44\,\mu m$) in the alumina and high attrition resistance are important for reducing dust.

Use of Stationary Calciners and Pneumatic Handling Systems for Alumina. The replacement of rotary alumina kilns by the energy-efficient stationary calciners has resulted in producing a different type of calcined alumina for smelter feed. This difference is reflected in the interrelationship between degree of calcination (measured by the mass loss on ignition), specific surface area, and the α-Al_2O_3 content [60].

The strength of the alumina particles has become of concern not only because of relatively higher breakdown in the stationary calciners, but also because of attrition occurring in pneumatic unloading and conveying equipment and in fluid-bed dry-scrubbing systems. The generation of fine particles in such equipment, apart from causing unacceptable dusting conditions in

the smelters, often results in troublesome segregation problems in alumina storage bins and bunkers.

Electrolyte Composition and Temperature. The trend to operate cells at lower temperatures with electrolyte having a lower bath ratio ($NaF : AlF_3$) has decreased the solubility and rate of dissolution of alumina in the electrolyte. The rate of dissolution is greater for aluminas having higher surface areas and low content of α-Al_2O_3. Both properties can be achieved by a low degree of calcination.

5.2. Typical Specifications for Metallurgical Alumina

The considerations discussed in Section 5.1 have contributed to the evolution of the general specifications used in production and international trading (Table 8). These values are only representative and considerable variation exists in actual practice depending on price, availability, smelting practices, and many other factors. Consistency of quality is a major consideration.

Table 8. Typical properties of metallurgical alumina

Physical property	
Particle size distribution, wt %	
+100 mesh (Tyler)	< 5
+325 (44 µm)	> 92
− 325	< 8
Bulk density, kg/L	
loose	0.95 – 1.00
packed	1.05 – 1.10
Specific surface area, m^2/g	50 – 80
Moisture (to 573 K), wt %	< 1.0
Loss on ignition (573 – 1473 K), wt %	< 1.0
Attrition index (modified Forsythe – Hertwig method)	increase in < 44 µm particles 4 – 15 wt %
α-Al_2O_3 content (by optical or X-ray method), %	< 20
Chemical analysis	wt %
Fe_2O_3	< 0.015
SiO_2	< 0.015
TiO_2	< 0.004
CaO	< 0.040
Na_2O	< 0.400

6. Industrial Alumina Chemicals

Alumina, in various forms, is one of the inorganic chemicals produced in greatest volume today. Although production of aluminum metal consumes ca. 90 % of all alumina, an increasing amount is being applied in the chemical industry for fillers, adsorbents, catalysts, ceramics, abrasives, and refractories. With the development and growth of applications and markets for alumina chemicals, all the major alumina producers have, over the years, converted a part of their capacity to produce various alumina chemicals. In fact, some of the older, smaller alumina refining plants have been totally converted to alumina chemicals production in order to be economically viable. Chemical uses account for nearly 8 % of the world production.

6.1. Aluminum Hydroxides

Aluminum hydroxides constitute a versatile group of industrial chemicals. Important uses requiring large quantities are as fillers in plastic and polymer systems and for the production of aluminum chemicals. A moderate amount is used for the production of alumina-based adsorbents and catalysts.

Aluminum hydroxide meets most of the requirements for an effective filler: white or near-white color; large volume production base, resulting in price and supply stability; consistency of physical and chemical properties; a wide range of particle size distributions; chemical inertness; and nontoxicity. However, its increasing popularity as a plastics filler is strongly related to its fire-retardant and smoke-suppressant properties, which justify the somewhat higher price compared with calcium carbonate and other mineral fillers. Aluminum hydroxide acts as a fire retardant by adsorbing heat through endothermic dehydration and dilution of pyrolytically produced combustion gas by the released steam. Dehydration and water release processes become significant at temperatures above 500 K. The smoke-inhibiting activity of aluminum hydroxide filler has been attributed to promotion of solid-phase charring in place of soot formation. Although offering these desirable features,

aluminum hydroxide has certain disadvantages that impose some limitations on its uses as a filler. Like other nonreinforcing mineral fillers, it generally lowers strength. Because it undergoes thermal decomposition, it is not suitable for processing above 500 K. These factors are responsible for the larger use of aluminum hydroxide in latex carpet backings and in glass-reinforced polyesters, where processing temperatures below about 480 K generally are used. These are also chemically cross-linked or fiber-reinforced systems, in which loss of strength caused by a nonreinforcing filler may not be very important. Aluminum hydroxide filler has been used less extensively in thermoplastics, e.g., poly(vinyl chloride) and polyethylene, and elastomeric materials. For use as a filler, the crystalline aluminum hydroxide from the Bayer process is dried and ground to particles $\leqq 10\,\mu m$ size. Special grades with increased whiteness and a variety of both particle size ranges and chemical purity also are available commercially.

Fine, precipitated aluminum hydroxide having a uniform particle size ($\approx 1\,\mu m$) is used in paper making as a filler pigment and as a coating. As a filler, it disperses rapidly with low sedimentation. Improved printing properties are reported for the hydroxide-filled paper. The application of fine, platy aluminum hydroxide as a paper coating is well established in the paper industry. It gives a coating of high brightness, opacity, and gloss (→ Paper and Pulp).

Technical aluminum hydroxide obtained from the Bayer process is 99.5 % pure. It dissolves readily in strong acids and bases. For these reasons, aluminum hydroxide is the preferred raw material for the production of a large number of aluminum compounds. These include pure, iron-free aluminum sulfate (used in the paper industry and for water purification), aluminum fluoride, synthetic zeolites, and sodium aluminate. Aluminum hydroxide also is used in the glass industry and in cosmetic and pharmaceutical preparations. An important cosmetic use of aluminum hydroxide is in toothpaste. The mildly abrasive hydroxide cleans and polishes teeth.

The price of aluminum hydroxides ranged from \$0.20 to \$0.60 per kg in 1990, the price range reflecting the cost of additional processing of the usual Bayer process product to suit application requirements. These include grinding, higher purity, classification, surface treatment, etc. Pharmaceutical-grade gel hydroxides were at the top of the price range.

6.2. Adsorbent and Catalytic Aluminas

Activated aluminas represent another group of technically important alumina chemicals. Principal uses are as drying agents, adsorbents, catalysts, and catalyst carriers. These products are obtained by thermal dehydration of different aluminum hydroxides in the 520 – 1070 K temperature range (see Section 1.5).

6.2.1. Preparation of Activated Aluminas

Bayer aluminum hydroxide is the chief source of commercial activated alumina products. Powder forms of activated alumina are produced by heating the hydroxide directly at 575 – 1825 K in ovens or in rotary or fluidized-bed calciners. The products have surface areas of 200 – 350 m^2/g and losses on ignition of 3 – 12 wt % (at 575 – 1473 K). Such products are used as decolorizing agents for organic chemicals and as starting material for the production of aluminum fluoride (→ Fluorine Compounds, Inorganic). Other uses include chromatographic and catalytic applications in organic chemistry.

Granular activated alumina produced from Bayer plant crust is one of the oldest commercial forms of this product and still is used widely. A flow sheet of the production process is shown in Figure 20. The activated material is a hard, nondusting product. Table 9 lists some properties of a commercial product of this type (Alcoa F-1). A similar granular product has been produced by compacting Bayer hydroxide by mechanical pressure (Martinswerk GmbH, Federal Republic of Germany). The process utilizes a roll-type compactor. The product from the compactor is broken up and sieved to the required size fractions and activated at 675 – 875 K in a rotary calciner.

Table 9. Typical properties of Alcoa activated aluminas

	F-1	H-151	S-100
Al_2O_3, %	92	90	95
Na_2O, %	0.58	1.6	0.35
SiO_2, %	0.12	2.0	0.03

Figure 20. Flow sheet for production of activated alumina from Bayer plant crust

Fast dehydration of Bayer aluminum hydroxide, either by vacuum or by exposure to high-temperature gas (1050 – 1300 K) for a few seconds, has been used for the production of ball-shaped, activated alumina having properties superior to the granular product. This process results in the formation of nearly amorphous ϱ-Al_2O_3. The product is finely ground and using water as binder, formed into spherical agglomerates in a rotating pan agglomerator. Rehydration of ϱ-Al_2O_3 with water leads to crystallization of bayerite, causing the agglomerates to harden. Reactivation of the hard balls at 675 – 775 K produces the activated product (5 – 20 mm in diameter) having a surface area of 320 – 380 m^2/g.

Alumina gels also have been used for the manufacture of activated aluminas. These gels are produced by neutralization of aluminum sulfate or ammonium alum by NH_4OH, or from sodium aluminate by neutralization with acids, CO_2, $NaHCO_3$, and $Al_2(SO_4)_3$. The gelatinous aluminum hydroxide precipitate is filtered and thoroughly washed and dried. The dried prod-

uct is activated, milled, and agglomerated to a spherical product. Other forming processes, such as extrusion, pelletizing, and tableting, also can be used. The product is finally activated at 675 – 875 K to a loss on ignition value of about 6 %. Although gels of various textures can be prepared, the usual industrial adsorbent products have very small pores (less than 4 nm in diameter) and surface areas in the range of 300 – 400 m^2/g. A flow sheet of a manufacturing process is shown in Figure 21. Table 9 reports data on a commercial, gel-based product (Alcoa H-151).

Figure 21. Production of gel-based activated alumina

Aluminum oxide hydroxide (boehmite), a by-product from the Ziegler process for linear alcohol production, is another source of activated alumina. The high purity of this material favors its use in catalytic applications. The fine-particle boehmite is normally extruded to various shapes. The material is claimed to serve as its own binder when peptized with glacial acetic acid. The extrudate is cut to the required size, dried, and activated at 775 – 875 K. The surface area of the activated product is 185 – 250 m^2/g. Commercial bayerite also has been used to produce activated alumina; the product is preferred in some catalytic applications.

6.2.2. Adsorbent Applications

A major application of activated alumina is in the field of adsorption, where its high surface area, pore structure, strength, and chemical inertness favor its use. The alumina performs important technical functions, such as gas and liquid drying, water purification, and selective adsorption in the petroleum industry.

Gases that have been dried successfully by alumina desiccants are:

acetylene	cracked gas	hydrogen	oxygen
air	ethane	hydrogen chloride	propane
ammonia	ethylene	hydrogen sulfide	propene
argon	freon	methane	sulfur dioxide
carbon dioxide	furnace gas	natural gas	
chlorine	helium	nitrogen	

In many applications an alumina desiccant can dry gas to a lower dew point than any other commercially available desiccant. The static water adsorption capacities of two typical activated aluminas (Alcoa F-1 and H-151) in contact with air at different relative humidity conditions are shown in Figure 22.

Figure 22. Static water adsorption capacity of typical commercial activated aluminas at 25 °C (298 K)

Moist gas usually is dried by passing it through a column (or tower) packed with the adsorbent. Adsorption of water on activated alumina is strongly exothermic, releasing between 45 and 55 kJ of heat per mole of water adsorbed. This factor must be considered in the design of the drying tower. Both granular and spherical forms of activated alumina can be used in desiccant beds. Sizes from 2 to 20 mm are available commercially. The granular products have lower

surface areas and their application is based on low cost per kilogram, low water load, and low stream pressure. Spherical products, produced by either the gel or the fast dehydration processes, have larger surface areas, a narrower pore structure, and a high adsorption capacity, and they are relatively more expensive than the granular variety. The spherical kind usually is specified for high-pressure, high-moisture removal duties. The alumina desiccant is regenerated by passing a current of hot, dry gas (475 K) through the bed, usually countercurrent to the main gas flow.

Liquids that can be dried with activated alumina include aromatic hydrocarbons, higher molecular mass alkanes, gasoline, kerosene, cyclohexane, power system coolants, lubricants, and many halogenated hydrocarbons. Liquids that are highly adsorbed on alumina (e.g., ethanol and methanol), react or polymerize in contact with activated alumina. Those containing components that tend to deposit on the alumina surface cannot be dried by activated alumina. Regeneration schemes for liquid dehydration units are varied and depend on the liquid being dried. In some applications the liquid being dried is vaporized, heated, and passed through the desiccant bed to adsorb water. Hot, dry gases also are used for regeneration.

An evolving application of activated alumina is in water purification. Several important contaminants have been removed from water successfully and economically in pilot plants as well as in large-scale treatment plants. These include reduction of fluoride concentration in drinking water and in some industrial effluents, and removal of color and odor from effluent water from dye works and paper mills. Removal of phosphate and arsenic also has been investigated.

Activated alumina can be used to separate one or more components from a gas or liquid stream by taking advantage of differences in adsorption or desorption kinetics. For example, a short cycle process has been used to recover heavy hydrocarbons from a stream of lighter hydrocarbons. Often a regeneration scheme can be devised that permits cyclic use of the alumina. In other instances, such as removal of catalyst in polyethylene and hydrogen peroxide production, it is more economical not to recycle the alumina.

6.2.3. Catalytic Applications

Alumina is used in many industrial catalytic processes, both as the catalyst and as a support for catalytically active components. In many instances, the alumina support contributes to catalytic activity and so assumes an essential role in the catalyst system. Other catalytic uses of alumina take advantage of its strength, heat resistance, and inertness.

Although the common adsorbent aluminas derived from Bayer hydroxide have many catalytic applications, high-purity materials (e.g., boehmite from the Ziegler process for linear alcohol production) are sometimes preferred. Because of the lower cost of Bayer process-based products, such techniques as water and acid washing of the activated product have been employed to reduce the alkali (Na_2O) content of the Bayer material. The sodium oxide is known to have a negative influence in many catalytic processes. Catalyst-forming methods include tableting, pelletizing, compacting, ball forming (agglomeration), and extrusion. Such factors as purity, surface area, pore volume, and size distribution, and rate of deactivation influence catalyst performance and selectivity. In addition, crushing strength and resistance to attrition of the catalyst pellets are important considerations in practical operation of catalytic reactors. Although these physical aspects of alumina catalysts are well characterized, the surface structure and chemistry responsible for catalytic activity still remains unclear. Many investigators have attributed catalytic activity to the intrinsic acidity of the surface of activated alumina. First, the combination of two neighboring OH^- groups to form water during the dehydration process leaves behind an exposed Al^{3+} ion, which, because of its electron deficiency, behaves as a Lewis acid site. In addition, hydroxyl groups are retained during thermal decomposition of aluminum hydroxide (see Section 1.5). These OH^- ions on the surface may act as proton donors (Brønsted acids). These Lewis and Brønsted acid sites have been looked upon as the active catalytic centers. Further "defect" structures are formed with increasing degree of dehydration [56]. Of the types of defects created during dehydration, those assumed to have the greatest catalytic importance are the triplet va-

cancies. They provide unusual exposure of the aluminum ions in the underlying layer and constitute strong acid sites.

Catalytic applications of alumina are extensive. Important industrial processes employing alumina as a catalyst by itself include alcohol dehydration and the Claus process for sulfur recovery (→ Sulfur). Dehydration of alcohols over activated alumina is one of the oldest catalytic processes. Typical reaction conditions for olefin production are 575 – 675 K and atmospheric pressure. Lower temperatures favor the formation of ethers. The most suitable aluminas for alcohol dehydration catalysis are those that have large surface areas (150 – 200 m^2/g) and possess good thermal and hydrothermal stability. Coke formation occurs over a period of several hundred operating hours and the catalyst must be regenerated by burning off the carbon with hot air at 773 – 873 K.

The largest present-day catalytic application of activated alumina itself is in the Claus process, which is used to recover sulfur from hydrogen sulfide (H_2S).

$$2\,H_2S + SO_2 \rightarrow 2\,H_2O + 3\,S \quad \Delta H = -147\,\text{kJ}$$

The reaction is carried out catalytically in two or more conversion stages using alumina catalysts. Reaction temperature in the first stage is around 625 K. At this temperature, the conversion of H_2S is only about 65 %. Subsequent lower temperature catalytic stages are used to further reduce the H_2S concentration. Spherical, high-strength activated alumina catalysts are used in the Claus converters. Service life as high as 5 years has been reported. Deactivation of the alumina catalyst occurs by sulfation, thermal aging, and carbon and/or sulfur deposition. Regeneration of Claus catalyst involves removal of sulfur and burning off of carbon deposits.

Alumina-supported catalysts are used extensively in the petroleum and chemical industries. In general, the petroleum industry catalysts have high surface area and high porosity; the support is mostly activated alumina. On the other hand, many typical chemical process catalysts (e.g., ammonia synthesis, steam reforming) are characterized by lower surface area ($< 20\,m^2/g$) and are nonporous or have very large diameter pores. The carrier in this case is inert and consists mostly of calcined or sintered alumina products.

Two different methods have been used commonly for preparation of alumina-supported catalysts: impregnation and coprecipitation. The alumina support used in the *impregnation process* generally has been formed into its final shape (extrudates, tablets) prior to the impregnation step. Impregnation with a salt solution of the active species is then carried out, followed by drying and thermal decomposition of the salt. In the *coprecipitation procedure,* hydroxides of aluminum together with the active component are precipitated from a salt solution by neutralization with ammonia or alkali. The washed precipitate is dried, powdered, and processed (e.g., by extrusion) to the desired shape and finally activated by thermal dehydration. The coprecipitation method is used when the active species must be present in high concentrations or when more uniform distribution of the active component is desired.

The technical and patent literature contains innumerable examples of the use of alumina as a catalyst support. Some important examples are the catalytic dehydration of *n*-butane to butadiene (used in synthetic rubber), using a chromia-impregnated alumina catalyst; molybdenum – alumina catalysts, used in hydrorefining operations (e.g., desulfurization) in petroleum refining; and pelleted catalysts containing platinum, palladium, and rhodium on an alumina base, used in automobile exhaust catalytic converters.

United States production of adsorbent-grade activated aluminas, both granular and spherical, amounted to nearly 250 000 t in 1990. Price of the cheaper, granular product was quoted around \$ 0.40 – 0.50 per kg. Price of the spherical product ranged from \$ 0.55 to \$0.65 per kg. Total catalytic applications of alumina in the United States were estimated to be around 400 000 t in 1990. Price of preformed alumina for catalytic applications ranges from \$ 0.60 to \$ 4.00 per kg, depending on source and purity. Alumina-based Claus catalyst was priced between \$ 3.00 and \$ 3.50 per kg.

7. Ceramic Uses of Alumina

Alumina is used extensively as a ceramic material (→ Ceramics, Advanced Structural Products). Products range from relatively low-calcined grades of polishing aluminas to the

extremely hard, fused alumina and synthetically produced sapphire. The characteristics that make alumina valuable in ceramic applications are high melting point (2325 K), hardness (9 on the Mohs scale), strength, dimensional stability, chemical inertness, and electrical insulating ability. These, together with availability in large quantities at moderate prices, have led to extensive and varied uses of alumina as a ceramic material.

7.1. Calcined Alumina

Ceramic aluminas are generally produced by calcining Bayer aluminum hydroxide at temperatures high enough for the formation of α-Al_2O_3. By control of calcination time and temperature and by the addition of mineralizers, such as fluorine and boron, the crystallite size in the calcined product can be varied from 0.2 to 100 µm. These calcined aluminas can be categorized broadly according to their sodium content. There are two general types: those having about 0.5 % Na_2O and low-soda grades with a content < 0.1 %.

Reactive alumina is a material manufactured by dry grinding calcined alumina to particle sizes smaller than 1 µm. The large surface area associated with very fine particles and the high packing densities obtainable considerably lower the temperatures required for sintering.

Tabular aluminas are manufactured by grinding, shaping, and sintering calcined alumina. The thermal treatment at 1900 – 2150 K causes the oxide to recrystallize into large, tabular crystals of 0.2 – 0.3 mm.

7.2. Fused Alumina

For ceramic applications and for the production of abrasives, fused aluminas are manufactured by melting a suitable raw material in an electric arc furnace (→ Abrasives). Calcined alumina from the Bayer process is used as a starting material for the highest quality fused alumina. Bauxites with varying levels of iron oxide, silicates, and titanium minerals are melted to produce the brown or less pure black qualities.

1. Introduction

Primary, secondary, and tertiary amines are distinguished on the basis of the number of hydrogen atoms in ammonia that have been replaced by organic groups. Substitution at the nitrogen atom by a fourth substituent gives quaternary ammonium compounds. The lower aliphatic amines are those with up to six carbon atoms per alkyl chain. Long-chain amines, with more than eight atoms per carbon chain, are generally known as fatty amines and are discussed in Chapter 7.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_001

In 1849, WURTZ prepared methylamines and ethylamines by hydrolysis of the corresponding alkyl isocyanates, trialkyl cyanurates, and alkylureas [1]. However, HOFMANN was the first to use the terms "primary", "secondary", and "tertiary" and to carry out fundamental work on the synthesis, properties, and structure of amines [2].

In general, naturally occurring amines are relatively complex compounds (e.g., alkaloids, vitamins, and amino acids); however, some lower alkylamines and diamines, such as tetramethylenediamine (putrescine) and pentamethylenediamine (cadaverine), are known as degradation or decomposition products of proteins.

With a worldwide production (2000) of several 100 000 t/a, the aliphatic amines are among the most important organic intermediates in the chemical industry. The range of uses of these compounds is correspondingly wide. Major uses include those in the production of agrochemicals (in particular, herbicides), dyes, drugs, surfactants, and plastics, as auxiliaries for the rubber, textile, and paper industries, and as anticorrosion agents and process chemicals for gas scrubbing.

2. General Chemical Properties

The chemistry of the aliphatic amines is determined by the electron lone pair on the nitrogen atom and by the tendency of the hydrogen atoms bonded to nitrogen to be replaced by other substituents.

2.1. Salt Formation

Because they carry alkyl substituents, the aliphatic amines are stronger bases than ammonia (see Table 1); with acids, they form salts that are very soluble in water but insoluble in organic solvents. This property, combined with the difference in solubility between amine and salt, makes amines good acid acceptors and solvents for gas scrubbing and for certain extraction processes (e.g., in the synthesis of semisynthetic penicillins).

2.2. Conversion to Carboxamides

Amines react with carboxylic acids and their esters, chlorides, and anhydrides to give the corresponding substituted carboxamides:

X = OH, OR, Cl

Very good yields are obtained, particularly with carboxylic acid chlorides, for which the reaction is highly exothermic. With carboxylic acids, the reaction often stops at the initially formed ammonium salt. This type of reaction is utilized industrially, for example, in the synthesis of various herbicides with an acid amide structure.

2.3. Conversion to Sulfonamides

The reaction with benzenesulfonyl chloride is utilized for distinguishing among primary, secondary, and tertiary amines (Hinsberg test), as well as for their preparative separation. Whereas primary amines form alkali-soluble *N*-alkyl benzenesulfonamides, secondary amines give alkali-insoluble *N,N*-dialkyl benzenesulfonamides, and tertiary amines do not react under these conditions. Limitations can arise with long-chain primary amines, which are alkali-insoluble despite their acidic hydrogen, and with tertiary amines, which may undergo quaternization with the sulfonyl chloride.

2.4. Reaction with Carbonyl Compounds

Depending on the reaction conditions and the compound employed, carbonyl compounds react with amines to form imines (Schiff bases) (**2**) or enamines (**3**); these products can be hydrogenated to give more highly alkylated amines. This reaction is an important method for synthesizing higher amines. The intermediate hemiaminals (**1**) are usually not isolable. Aldehydes generally react faster than ketones. Secondary amines can only form enamines, and tertiary amines neither of the two products.

An amine, an aldehyde, and a compound with an activated hydrogen atom, such as a ketone, can react to form a Mannich base.

In this case, the condensation product between the aldehyde and the amine is attacked by the C – H acidic compound, in this case the ketone.

2.5. Reaction with Carbon Dioxide and Carbon Disulfide

The carbamic acid or dithiocarbamic acid formed in this reaction is unstable but can be isolated as a salt or an ester.

Dithiocarbamates obtained from various amines play a key role as vulcanization accelerators in the rubber industry.

2.6. Reaction with Epoxides

Primary amines react with epoxides to give a mixture of mono- and dioxyalkylated derivatives, whereas secondary amines give only monooxyalkylated compounds, and tertiary amines form quaternary ammonium compounds.

This oxyalkylation reaction is one of the most important industrial reactions of aliphatic amines and is utilized for the preparation of flocculants, surface coating resins, drug intermediates, and products for gas scrubbing (→ Ethanolamines and Propanolamines).

2.7. Alkylation

The reaction of amines with alkyl halides and dialkyl sulfates to give, ultimately, quaternary ammonium compounds is utilized in preparative pharmaceutical chemistry and for the preparation of anticorrosion agents and biocides.

The reaction of alkyl halides with ammonia is not very useful for the preparation of primary or secondary amines since these are stronger bases and preferentially attack the halides. Tertiary amines can be prepared, though. On a laboratory scale, primary amines can be obtained by using tetramethylenehexamine, and secondary amines with cyanamide.

2.8. Formation of Isocyanates and Ureas

The reaction of phosgene with primary amines leads first to the corresponding carbonyl chloride; subsequent cleavage of hydrogen chloride

gives the alkyl isocyanate. Excess amine reacts with the isocyanate with formation of ureas:

This reaction is important in the preparation of various herbicides with urea, carbamate, or thiocarbamate structures and, particularly in the case of polyfunctional amines, in polyurethane chemistry. The reaction of secondary amines with phosgene proceeds via an analogous intermediate chloride to form *N*,*N*′-tetraalkylureas.

2.9. Reaction with Acrylonitrile

The addition of a primary or secondary amine to acrylonitrile to form an aminopropionitrile is utilized industrially on a large scale for the preparation of higher diamines and polyamines, because the nitrile can be readily hydrogenated to the amine.

$$RNH_2 + CH_2{=}CHCN \longrightarrow RNHCH_2CH_2CN$$
$$[\longrightarrow RNH(CH_2)_3NH_2]$$

2.10. Formation of Isonitriles

Primary amines react with trichloromethane under basic conditions to form isonitriles:

$$RNH_2 + CHCl_3 + 3\,KOH \longrightarrow RNC + 3\,KCl + 3\,H_2O$$

Because of the strong unpleasant odor of the isonitriles, the reaction can be used as a test for primary amines. For the lower amines, the reaction can be used synthetically as well. An alternative route uses the *N*-alkylformamides to synthesize isonitriles.

2.11. Oxidation

In contrast to their salts, the free amines are sensitive to oxidation, giving various products, depending on the oxidizing agent and the type of amine. Tertiary amines are oxidized by hydrogen peroxide to amine oxides, whereas the corresponding compounds formed from primary and secondary amines undergo further reaction to give the corresponding hydroxylamines or aldoximes:

Oxidation with nitrous acid can be used to distinguish among primary, secondary, and tertiary amines. Primary amines undergo diazotization followed by loss of gaseous nitrogen and afford alcohols by reaction of the intermediate carbenium ion with water. Secondary amines react to give yellow *N*-nitrosoamines. Normally, tertiary amines do not react.

$$RCH_2NH_2 + HNO_2 \longrightarrow RCH_2OH + H_2O + N_2$$

$$(RCH_2)_2NH + HNO_2 \longrightarrow (RCH_2)_2N{-}N{=}O + H_2O$$

The formation of nitrosamines can be a serious problem, particulary with secondary amines, since they are highly mutagenic. During normal use they are not formed, but upon contact with nitrites or nitrous oxides traces can be produced that give rise to problems during handling. Air contamination with secondary amines is thus considered quite problematic.

2.12. Dealkylation

Tertiary amines can be dealkylated by converting them to basic quaternary ammonium salts, which decompose upon heating. If only methyl groups are present, they are eliminated as methanol or dimethyl ether; all higher alkyl groups furnish alkenes, e.g.,

This reaction, known as the Hofmann degradation, is seldom utilized synthetically, but used to be important for elucidating the structure of unknown amines.

3. General Production Methods

3.1. Production from Alcohols

The reaction of the appropriate alcohol with ammonia over a suitable catalyst is now the most common process for the preparation of lower alkylamines. In this reaction, the product is always a mixture of primary, secondary, and tertiary amines because the primary amine formed initially can react further with one or two molecules of alcohol. While the initial conversion of the alcohol to the primary amine is close to thermoneutral, the formation of secondary and tertiary amines is exothermic and thus thermodynamically favored. Also, the primary amine is more nucleophilic than ammonia and hence has a higher reactivity. The product distribution can be controlled to a certain extent by means of the reaction conditions (temperature, excess of ammonia, residence time). Because the mixture of products usually obtained does not correspond to market requirements, amines that are not marketable can be recycled. Thus, the yield of the desired amine can be increased to above 90 %.

Previously, this reaction was carried out with pure dehydration catalysts (e.g., alumina, silica, titania, thorium oxide, tungsten oxide, chromium oxides, phosphates or various mixed oxides such as silica – alumina, clays, or zeolites [3]) and temperatures up to 500 °C; however, use of these catalysts is now restricted to the production of methylamines. For the conversion of an alcohol containing two or more carbon atoms, catalysts possessing hydrogenating and dehydrogenating properties have become important. The catalysts used are mainly based on nickel, cobalt, copper or iron, and to a lesser extent platinum or palladium. Noble metal catalysts have a tendency to cause C – C or C – N bond cleavage and can hence give lower selectivities. Promoters such as Ag, Zn, In, Mn, Mo, and alkali metals are added to improve catalyst performance. Mostly, the active components are supported on a carrier such as Al_2O_3, SiO_2, or ZrO_2. Zeolites have been suggested as carriers to improve the selectivity towards primary amines [4]. In this process, the alcohol, ammonia, and hydrogen are passed continuously over the catalyst in a fixed-bed reactor. The reaction takes place at about 0.5 – 25 MPa and about 100 – 250 °C, depending on the catalyst and on whether the liquid-phase or the gas-phase process is used.

Mechanistic details of the process have been reviewed [5]. The first and rate-determining step is the dehydrogenation of the alcohol to the carbonyl compound. Addition of ammonia is followed by loss of water to yield an imine or an enamine, which is hydrogenated to the final amine. Side reactions are amine disproportionation, especially at higher reaction temperatures, and to a lesser degree aldol condensation of the intermediate aldehydes, formation of Schiff base from these aldehydes and the amine product, and nitrile formation, which occurs at high temperatures and low hydrogen pressures.

A two- to eightfold excess of ammonia is used to shift the equilibrium towards the primary amines. Although hydrogen is not required as a direct reactant, in its absence imines, enamines, and even nitriles are formed. Hydrogen also maintains the activity of the catalyst by removing carbonaceous deposits and metal carbides or nitrides and prevents disproportionation of the amine products [6]. The various versions of the process have been reviewed in detail [7]. Several surface-bound intermediates were identified

by Fourier transform IR spectroscopy [8]. While the amination of diols and polyols in principle follows the same rules as for the monools, the occurrence of numerous side reactions, for instance, cyclizations, is a complicating factor [9].

The same method is also useful for alkylating primary or secondary amines instead of ammonia. When an amine and an alcohol having different aliphatic substituents react, the product is a mixed aliphatic amine. For example, *N*,*N*-dimethylethylamine can be obtained from dimethylamine and ethanol. To avoid transalkylation at the nitrogen atom in reactions of this type, copper catalysts are recommended [10]. Copper chromite is a particularly effective catalyst for long-chain tertiary amines such as dimethyldodecylamine [11].

3.2. Production from Carbonyl Compounds

Aldehydes and ketones are used in preference to alcohols for amine synthesis if this is more economical. Generally, this is the case only for the lower aldehydes (obtained from oxo synthesis) and acetone obtained as a byproduct in the production of phenol (Hock synthesis).

The reaction between a carbonyl compound and ammonia or an amine occurs in two steps: the imine or Schiff base formed initially is hydrogenated with hydrogen in a second step to give the amine. The usual procedure is similar to that for the conversion of alcohols; the reaction mixture, comprising the carbonyl compound, ammonia and hydrogen, is passed over a fixed-bed catalyst. In some cases, it can be advantageous to carry out the reaction in two stages. The carbonyl compound and ammonia or the amine react first, the water of reaction is removed, and only then is the hydrogenation carried out [12].

The essential difference between the amination of an aldehyde or ketone and that of an alcohol is that in the former hydrogen is a reactant and is consumed in a stoichiometric amount. The substantially higher heat of reaction of this process (e.g., 60.4 kJ/mol for acetone [13] versus 7.1 kJ/mol for isopropyl alcohol) necessitates a fundamentally different reactor design. In general, the process is carried out in the vapor phase at 100 – 160 °C and atmospheric or slightly above atmospheric pressure. High-pressure processes can also be employed if the heat of reaction can be removed by appropriate measures, such as a high recycle rate or with a multitubular reactor. Since the reaction temperatures are lower than for the reaction of alcohols, in principle, higher selectivities can be achieved.

Generally, the same catalysts as for the hydrogenative amination of alcohols can be used; control of product distribution by adjusting the amount of excess ammonia and workup by distillation are also much the same. Comprehensive reviews of industrial and preparative possibilities for synthesis of amines from carbonyl compounds are available [7], [14].

It is also possible to use other reducing agents instead of hydrogen, but these are of little industrial importance. This is often due to the difficulty of handling and the cost of the reagents (e.g., selenophenol or $NaBH_4$). The Leuckart – Wallach reaction, in which ammonium formate is used to aminate the carbonyl compound with formation of CO_2 as byproduct, has found some use.

3.3. Production from Nitriles

Frequently, nitriles can be obtained more economically than the corresponding alcohols or carbonyl compounds. They are synthesized by ammoxidation, the addition of an amine or an alcohol to acrylonitrile, or from the corresponding carboxylic acid. Nitriles are converted into the corresponding amines, preferably by catalytic hydrogenation:

Noble metal (palladium, platinum, rhodium), nickel, or cobalt catalysts are generally em-

ployed, but iron catalysts have been used to an increasing extent [15], largely for economic reasons. Whereas the supported noble metals permit the use of relatively mild reaction conditions (20 – 100 °C, 0.1 – 0.5 MPa), pressures as high as 25 MPa and temperatures of up to 180 °C are required with nickel or cobalt catalysts. When di- or polynitriles are hydrogenated to di- or polyamines, a base such as NaOH is often added to the catalyst [16]. There are various versions of the process, but those most often used are the batch process with a suspended catalyst and the continuous process with a fixed-bed catalyst.

Side reactions resulting in the formation of secondary amines always occur, but these can be suppressed by the addition of ammonia, sodium hydroxide solution, or an acid [7]. Alternatively, process conditions can be adjusted to make the formation of secondary or tertiary amines the principal reaction. This alternative is of interest, for example, in the synthesis of di- and triethylamines from acetonitrile [17] or dibutylamine from butyronitrile [18].

The hydrogenation of acrylonitrile is a special case. Whereas saturated amines are normally the only products of this reaction, the use of copper chromite as a catalyst instead of noble metals, nickel, or cobalt leads to allylamine and diallylamine [19].

Many important nitrile hydrogenations to form the corresponding amines are based on previous addition reactions of acrylonitrile. Alcohols add to acrylonitrile only in the presence of a basic catalyst such as NaOH, KOH, or quaternary ammonium hydroxides. Since amines are themselves sufficiently basic, addition occurs readily. Sometimes higher temperatures are needed for cyanoethylation, and stabilizers have been described to avoid polymerization of acrylonitrile [20].

3.4. Production from Alkyl Halides

The reaction of an alkyl halide with ammonia or an amine gives an alkylammonium halide, from which the amine can be liberated with a caustic alkali solution. Although a standard method of preparative chemistry, this route is industrially important only for the preparation of ethylenediamine, the homologous polyamines, and a few special amines such as allylamine and some small-volume pharmaceuticals. The reasons for this restricted use are the lack of cheap starting materials, corrosion and product-quality problems that arise in the processing of halides, and the need to dispose of the salt that is formed.

3.5. Production from Nitro Compounds

Whereas the reduction of nitro compounds is one of the most important methods for the synthesis of aromatic amines, this route has not become important for the production of aliphatic amines. Because the availability of appropriate nitroalkanes is restricted, this method is used only in a few special cases, e.g., the production of 2-amino-1-butanol, the precursor for the antituberculotic ethambutol.

The reduction proceeds via the nitroso or hydroxylamine intermediate, in some cases even at room temperature, and gives the amine in yields of 90 % or more. Platinum, palladium, rhodium, nickel, or copper is used as the hydrogenation catalyst [7]. The reaction is highly exothermic (ca. 500 kJ/mol per nitro group), and therefore heat must be removed rapidly to control the process. Nitroparaffins are more difficult to hydrogenate than their aromatic counterparts [21].

Functionalization of alkenes with NO or NO_2 has been described; the reaction follows a radical path and affords a mixture of products, among them nitroalkenes. Reduction of the latter also leads to amines, but has found no industrial application so far. Likewise, primary amines were obtained from paraffins by nitration with HNO_3 or liquid NO_2 and hydrogenation of the resulting nitroparaffin/ketone mixture in the presence of ammonia [22]. The preparation of 1,2-diamines from nitroolefins and *O*-alkylhydroxylamines has been described [23].

3.6. Production from Olefins

Amines having a tertiary alkyl group adjacent to the nitrogen atom (e.g., *tert*-butylamine) are difficult to obtain by conventional synthetic methods. These compounds can be prepared readily by addition of hydrogen cyanide to an alkene, e.g., 2-methylpropene, in an acidic medium:

This process, known as the Ritter reaction [24], is carried out at 30 – 60 °C, and the resulting formamide intermediate is hydrolyzed when the reaction mixture is heated to ca. 100 °C. To liberate the amine, the acidic mixture is neutralized to give sodium formate and the salt of the original acid, i.e., sodium sulfate. Because hydrocyanic acid is difficult to handle and causes corrosion problems, one carbon atom is lost as formate, and significant amounts of salts (ca. 3.3 kg/kg *tert*-butylamine) must be disposed of in deep wells, this process is restricted to amines that cannot be obtained by one of the methods described in Sections 3.1, 3.2, 3.3, 3.4, and 3.5. Besides *tert*-butylamine and *tert*-octylamine, these are only a few amines of pharmaceutical interest.

Although advantageous thermodynamically, the direct addition of ammonia or an amine to an olefinic double bond is restricted to a few cases in which either an activated amine or a compound with an activated double bond is employed, for example, the addition of an amine to acrylonitrile. It is however possible to achieve the addition of ammonia to unactivated alkenes under pressure and by using catalysts. The most effective catalysts are acidic zeolites. The first successful demonstration was the formation of ethylamines from ethylene and ammonia with H-mordenite [25]. Although the conversion for the direct amination of alkenes is low, being limited by kinetic factors and the thermodynamic equilibrium, the selectivity for monoalkylamines can be excellent given the proper choice of zeolite and alkene. Small-pore zeolites are most suitable for ethylamines [26], while medium-pore zeolites can be used to prepare *tert*-butylamine [27]. Certain large-pore zeolites have been found to offer improvements over medium-pore zeolites [28–30].

Homogeneously catalyzed amination of alkenes is restricted to some special cases [31], [32]. Although not very selective, hydroformylation of alkenes in the presence of ammonia or amines [33] might find applications in future. So far it is hampered by the fact that in addition to the amines arising from the *n*-aldehyde and isoaldehyde, significant amounts of alcohols are formed besides dimerization products [34].

3.7. Other Processes

The hydrogenation of aromatic amines to cycloalkylamines is industrially restricted to the production of cyclohexylamines (see Chap. 5). A process for synthesizing amines from carbon monoxide, hydrogen, and ammonia or amines over an activated iron catalyst by a method of the Fischer – Tropsch-type was described [35], but this is not used on an industrial scale. All other synthetic routes described in the literature, for instance reduction of amides [36], are so far essentially laboratory methods that are suitable for the preparation of small quantities and are carried out on an industrial scale only in isolated cases. For details see [3].

4. Lower Alkylamines

4.1. Physical Properties

Ethylamine is gaseous at room temperature; diethylamine, triethylamine, and higher amines up to about twelve carbon atoms per alkyl chain are liquid, and long-chain amines containing still higher alkyl groups are solid.

The short-chain amines are readily soluble in water, alcohol, ether, and conventional organic solvents. Amines containing more than five carbon atoms are only partially or very sparingly soluble in water. The solubility in water generally decreases with increasing temperature, and in some cases the miscibility gap vanishes at lower temperatures. For example, triethylamine is completely miscible with water below about 18 °C but is only partially miscible with water above this temperature. Therefore, industrial phase separations (amine/water) are often carried out at elevated temperatures.

All alkylamines, but particularly the lower members, which have high vapor pressures, have a characteristic ammonia odor. The odor decreases with increasing substitution.

Physical properties of importance for characterizing and handling the alkylamines are summarized in Table 1. For further data, reference may be made to the relevant tables and the producers' data sheets.

4.2. Storage and Transportation

The aliphatic amines are usually stored in carbon steel or stainless steel containers; relatively small amounts can be kept in glass or ceramic vessels. Nonferrous metals such as copper, aluminum, zinc, lead, and their alloys (e.g., brass) are not resistant to amines. Aqueous amine solutions are basic and slowly etch glass. Ethylamine must be stored under pressure because it boils below room temperature. Isopropylamine (*bp* 32.4 °C) is usually stored in cooled and isolated tanks or in pressurized containers. To facilitate storage and transport, these amines are also produced and distributed in the form of aqueous solutions (e.g., 40 % or 70 %). The aliphatic amines have a virtually unlimited shelf life, but they should be stored under nitrogen to avoid contact with carbon dioxide (resulting in formation of carbamates) and atmospheric moisture.

All of the amines discussed here are inflammable. Some of them have very low flash points (see Table 1), and they form explosive mixtures with air. Hence, when these compounds are stored and transported, the relevant statutory regulations for inflammable liquids or pressurized gases must be observed. Because these vary greatly from country to country, they cannot be discussed in detail here.

To prevent odor nuisance (odor thresholds are below 0.1 ppm in some cases) and impermissible emissions, special precautions must be taken during storage and, in particular, during transfer from one container to another. Where the process cannot be carried out in a closed system and relatively large amounts are handled, absorption plants for washing off-gas must be provided. Scrubbing with water is frequently adequate, but better treatment of off-gas is achieved by scrubbing with an acid. For smaller plants, adsorption on active carbon filters is advisable under certain circumstances. This method has the additional advantage that the adsorbed amines can be recovered.

The toxicity (Chap. 10) of these amines also makes it necessary to take certain precautions with regard to occupational safety. These include, in particular, avoiding inhalation of amine vapors by using respiratory equipment and reliable prevention of skin and eye contact with fluid amines by wearing protective clothing.

4.3. Quality Specifications and Analysis

In the case of individual amines, the quality specifications are very high. Particularly for amines with a wide range of uses (e.g., ethylamine), specifications require a purity of above 99.7 %, although usually 98.0 – 99.5 % purity is considered adequate. Some end uses impose additional maximum values on the content of water, ammonia, and unsaturated amines or, in the case of tertiary amines, on the content of primary and secondary amines.

The amine content is determined by acid titration of the basic nitrogen, and the purity is determined preferably by gas chromatography. Also of importance is the determination of the water content by the Karl Fischer method, titration of the imine content by oximation, and the determination of physical properties.

4.4. Production

With few exceptions, aliphatic amines of industrial importance are produced by any one of the methods described in Chapter 3. The main routes start from the corresponding hydroxyl or carbonyl compounds. The choice of process depends mainly on the following criteria:

1) Price of the starting materials
2) Availability of the starting materials
3) Conversion of any existing plants to allow for different pressures in the two processes
4) Availability of hydrogen (hydrogen consumption and pressure differ in the two processes)
5) Fiscal reasons (taxes or subsidies on particular materials, e.g., ethanol)

Because these factors vary greatly from country to country, and in some cases even from region to region, and are changing continually, the

reasons for the choice of a particular process depend strongly on individual circumstances. Currently (2000) the commercial use of the alcohol route is prevalent.

The aliphatic amines of large-scale industrial importance (mainly C_2-C_4) can be produced in a multipurpose plant that can be used for the production of various amines under similar reaction conditions, with only small differences in workup.

The reaction of an alkyl halide with ammonia or an amine typically results in formation of sodium halide as an undesired byproduct. This synthetic route is used for ethylenediamine and special amines such as allylamines (Chapter 3.4). Ethylenediamine can also be produced from ethanolamine and ammonia or directly from ethylene oxide.

Other production processes have become important only for a few amines. Examples are the production of *tert*-butylamine from isobutene and hydrogen cyanide or, since 1987, by direct amination [37] (Section 3.6).

Another industrial route to alkylamines is the addition of amines to acrylonitrile followed by hydrogenation. Examples are 1,3-diaminopropane and dipropylenetriamine, produced by combination of ammonia and acrylonitrile and subsequent hydrogenation, and the hydrogenation of 3-alkoxypropionitriles, which are produced by addition of alcohols to acrylonitrile to give 3-alkoxypropylamines (Section 3.3).

When the conversion of alcohol to amine is performed in the liquid phase under high pressure (typically 20 MPa) the plant can consist of a synthesis unit with a cylindrical reactor, heat exchangers, high- and medium-pressure (3 MPa) separators and a distillation unit. The distillation towers separate ammonia/low-boiling alkylamine, water, and high-boiling residues and remove the monoalkylamine from di- and trialkylamine. Ammonia/low-boiling alkylamine is generally used in excess and recycled to the synthesis reactor. Water is typically isolated by phase separation and fed to a wastewater treatment system. If the reaction mixture does not meet market requirements, the excess amines can be returned to synthesis stage since the mono-, di-, and trialkylamines are in thermodynamic equilibrium (see Section 3.1).

Reactions in the gas phase are typically carried out in low-pressure reactor systems which

require only one gas – liquid separator (3 MPa) and can be set up with cheaper equipment. Figure 1 shows a simplified flow diagram of the catalytic gas-phase reaction of ethanol with ammonia. In this case all three ethylamines are separated in a specially designed distillation unit and marketed.

To construct a multipurpose plant, it must first be decided whether the synthesis is to be run at low to medium (0.1 – 3 MPa) or high pressure (5 – 30 MPa). The design of the distillation unit depends on the range of amines to be produced. For the whole range of lower alkylamines (starting with ethylamines) a complicated system of five to six distillation towers is needed. With three distillation towers, a plant for a restricted portfolio of alkylamines can be run. The first pressure tower (typically 1.5 – 1.8 MPa) separates ammonia/low-boiling amine, the second water, and the third the desired alkylamine. The excess amines are reycled to the synthesis unit. For instance, a monoalkylamine can be produced by feeding pure alcohol and ammonia or by feeding recycled di- and trialkylamines, fresh alcohol, and ammonia. Instead of ammonia low-boiling amines such as methylamine or dimethylamine can be used for the synthesis of mixed amines. An example is the production of *N,N*-dimethylethylamine from ethanol and dimethylamine.

4.5. Uses

Ethylamines. Of the amines discussed here, with a worldwide market volume (2000) of about 80 000 t/a, the ethylamines are the most important lower aliphatic alkylamines. For tax reasons, in Japan ethylamines are produced from acetaldehyde, while in other countries ethanol is mostly used. The general production processes are similar; differences lie in the catalyst used, the distillation conditions, and the recycle streams (e.g., [39]). Production of di- and triethylamine from acetonitrile is described in [17].

The principal use of *monoethylamine* is in the production of herbicides of the triazine type by reaction with cyanuric chloride. Important commercial products are atrazine (Novartis), ametryne (Novartis), cyanazine (ACC, DuPont), simazine (Novartis), terbutryn (Novartis), desmetryn (Novartis), terbumeton (Novartis), secbumeton (Novartis), simetryn (Novartis) and terbutylazine. Lately, the demand for atrazine has decreased due to environmental concerns, and it has been banned in certain western European countries. A triazine derivative has also been suggested as stabilizer for chlorine in swimming pools [40]. Ethylamine, via *N*-ethylcyclohexylamine, also ends up in the herbicide cycloate (see below). The fungicide cymoxanil (DuPont) is also made from ethylamine. The ethylamine demand for rubber applications, for instance, toluene ethylsulfonamide, is declining.

A large percentage of the total *diethylamine* production is used for *N,N*-diethylaminoethanol, which is formed by reaction with ethylene oxide and finds application as a corrosion inhibitor and in coatings. Diethylamine is also used for the production of vulcanization accelerators. Reaction with carbon disulfide gives a dithiocarbamate that can be oxidized to a thiuram disulfide. The most important commercial products are sodium and zinc diethyldithiocarbamate and tetraethylthiuram disulfide. Diethylamine is used for the production of certain agrochemicals, such as rice herbicides [e.g., Napropamide (Zeneca) and Thiobencarb (Kumiai)] or insecticides [e.g., Phosphamidon (Novartis, DuPont) and Pirimiphos-methyl (Zeneca)], pharmaceuticals, radical scavengers (diethylhydroxylamine), and insect repellents (*N,N*-diethyl-3-methylbenzamide, Autan).

Of the three ethylamines, *triethylamine* has the widest range of uses and is also the most expensive product owing to the unfavorable distribution of monoethylamine, diethylamine, and triethylamine in production. Much of the triethylamine is used as an organic acid acceptor in synthesis or as a salt former in precipitation and purification operations. Important examples of these uses are in the synthesis of semisynthetic penicillins and cephalosporins, and as solubilizers for herbicides in combination with 2,4-dichlorophenoxyacetic acid or 2,4,5-trichlorophenoxyacetic acid. Triethylammonium is the cationic component of the herbicide Garlon 3A (Dow Elanco). Other important fields of use include polyurethane catalysts (for example, the hardening of core sands in cold-box casting), curing catalyst for phenol – formaldehyde resins, anticorrosion

Figure 1. Continuous process for the production of ethylamines [38]

agents, paper, textile and photographic auxiliaries, and anodic electrocoating.

Propylamines. The commercial demand for *n*-propylamines and isopropylamines is together about the same as that for the ethylamines. *Monoisopropylamine* is the most important product and is used particularly in the production of herbicides such as bentazon (BASF), Roundup (Monsanto), imazapyr (ACC) and the triazines ametryne (Novartis), atrazine (Novartis), desmetryn (Novartis), prometryn (Novartis), pramitol (Novartis), dipropetryn (Novartis), and propazine (Novartis, Makteshim-Agan and Drexel). Other applications encompass the nematicide fenamiphos (Bayer), the fungicide iprodione (Rhône-Poulenc), insecticides, pharmaceuticals, and surfactants.

Dipropylamine is required principally as a starting material for the synthesis of herbicides, e.g., trifluralin (Dow), oryzalin (Dow), EPTC (Zeneca), and vernolate (Zeneca). The other propylamines are of minor importance compared to monoisopropylamine and dipropylamine. *Diisopropylamine* is mostly used for agrochemicals such as the herbicides diallate and triallate (Monsanto), but also for rubber accelerators such as DIBS (*N,N*-diisopropyl-2-benzothiazylsulfenamide). *n-Propylamine* is used for agrochemicals and pharmaceuticals. *Tripropylamine* is an intermediate for pharmaceuticals and corrosion inhibitors.

Butylamines. *Diisobutylamine* is the principal starting material for the herbicide Butylate (Zeneca). *tert-Butylamine* is primarily employed for the synthesis of vulcanization accelerators, for instance, TBBS (*N-tert*-butyl-2-benzothiazylsulfenamide) and TBSI (*N-tert*-butyl-2-benzothiazylsulfenimide). *tert*-Butylamine is also used for the production of herbicides, i.e., terbacil (DuPont) and the triazines terbutylazine, terbumeton (Novartis), and terbutryn (Novartis) and insecticides (e.g., diafenthiuron from Novartis). A derivative has also been proposed as stabilizer for cosmetics [41]. The synthesis of vulcanization accelerators of the sulfenamide type is an important outlet for *dibutylamine* (e.g., sodium dibutylthiocarbamate, zinc dibutyldithiocarbamate or tetrabutylthiuram disulfide); the demand for this amine for other purposes (e.g., corrosion protection, flotation agents, cutting oils, plastics, and intermediates for insecticides (e.g., carbosulfan) and pharmaceuticals) is less important.

Monobutylamine is an intermediate for the production of plasticizers (e.g., the rubber accelerator dibutylthiourea), agrochemicals (e.g., DuPont's fungicide benomyl), pharmaceuticals (e.g., the antidiabetic tolbutamide), emulsifying agents, dyes, and UV absorbers.

Tributylamine is also used commercially (a few 100 t/a) as a polymerization catalyst and as an acid acceptor. *sec-Butylamine* is consumed in small amounts for herbicides such as bromacil (DuPont) or secbumeton (Novartis).

Other Amines. Of the C_{4+} monoamines, only few are of commercial importance. *Octylamine* is required, for example, for the production of biocides, as a solvent for pesticides, and as precursor for *N*-octylpyrrolidone – which is used for the cleaning of printing machines – whereas *2-ethylhexylamine* is employed for the production of oil additives and for insecticides. *Di-2-ethylhexylamine* is used for oil additives, dyes, and pharmaceutical applications. *Tri-2-ethylhexylamine* (*bp* 337.9 °C) is also commercially available and mainly used in coatings. *Tridecylamine* (mixture of isomers) is used for the production of the fungicide tridemorph (BASF). A mixture of the *pentylamines* finds use in drilling applications. *N,N-Dimethylethylamine* is an important epoxy and urethane catalyst, for instance, in sand-core applications. It is made from ethanol and dimethylamine. *N,N-Dimethylisopropylamine*, usually obtained from acetone and dimethylamine under hydrogenating conditions, is also used in foundry applications. *N-Ethyldiisopropylamine* (Hünig's base) finds use as a good acid acceptor. *Mono-*, *di-*, and *trihexylamine* are also commercially available, but represent very minor products. *Isoamylamine* (3-methyl-1-butaneamine) is an intermediate for pharmaceuticals and agrochemicals.

Some 10 000 t/a of tertiary alkyl primary amines are manufactured by Rohm & Haas by means of the Ritter reaction. These primene amines range from *tert*-octylamine to C_{18} – C_{22}.

Of the unsaturated amines, *diallylamine* has the most significant market (ca. 1000 t/a); it is used for the production of *N,N*-diallyldichloracetamide. Copolymers of dimethyldiallylammonium chloride with acrylates or acrylamides are used for water treatment. *N-Ethylmethallylamine* is employed for herbicide production (Dow's sonalan).

Although *chloroalkylamines* (mainly chloroethyl- and chloropropyl-*N,N*-dialkylamines) are not important in terms of the amounts employed, they are important starting materials for the production of a number of pharmaceuticals (principally neuroleptics).

Although not a lower alkylamine, *polyisobutenamine* (PIBA) is produced with the same technology by amination of the hydroformylation product of polyisobutene (PIB) with a molecular mass of about 1000 [42]. About 10 000 t/a PIBA is used as an detergent in finished additive packages for gasoline to improve the mechanical functioning of the engine, lower fuel consumption, and give improved emission characteristics.

4.6. Economic Aspects

Worldwide production capacity for aliphatic amines including fatty amines but excluding methylamines is estimated to be ca. 500 000 t/a, of which about 40 % is attributable to the United States and about 30 % to western Europe. Because of the large number of producers and the varying capacities of multipurpose plants, exact figures for annual worldwide production are not available. Apart from those who produce mainly for their own requirements, the most important producers of lower aliphatic amines are Air Products, Hoechst Celanese, and Elf Atochem in the United States; BASF, Elf Atochem, Hoechst Celanese, and ICI in Western Europe; Daicel in Japan; and Nordeste/Oxiteno in Brazil.

Manufacturing costs vary significantly depending on the availability of the starting materials and the type of process, e.g., continuous dedicated plant vs. batch process in a multipurpose plant.

5. Cycloalkylamines

Cyclopentylamine [*1003-03-8*], aminocyclopentane, $C_5H_{11}N$, M_r 85.15, is a colorless liquid, *mp* −85 °C, *bp* 106 – 108 °C (at 101.3 kPa), d_4^{20} 0.8689, n_D^{20} 1.4482, flash point 17 °C, with an ammoniacal odor.

Production. Cyclopentylamine is produced from cyclopentanone and ammonia over nickel

catalysts at 20 MPa and 150 – 200 °C in the presence of circulating hydrogen over a fixed-bed catalyst.

Uses. Cyclopentylamine is used in small amounts as an intermediate for the potato and rice fungizide pencycuron (Bayer, Nihon Tokushu, Noyaku Seizo).

Cyclohexylamine [*108-91-8*], aminocyclohexane, cyclohexanamine, hexahydroaniline, hexahydrobenzenamine, aminohexahydrobenzene, $C_6H_{13}N$, M_r 99.18, is a colorless liquid, *mp* − 17.8 °C, *bp* 134.5 °C (at 101.3 kPa), d_4^{25} 0.8647, n_D^{20} 1.4592.

Viscosity

Heat of vaporization	399.86 J/g
Flash point (closed cups)	26.5 °C
Ignition temperature (class T3)	265 °C
Ignition range in air	1.6 – 9.4 vol %

Cyclohexylamine is infinitely miscible with water and conventional organic solvents. With water it forms an azeotrope that contains 44.2 % cyclohexylamine and boils at 96.4 °C.

Chemical Properties. Chemically cyclohexylamine has much in common with the acyclic aliphatic amines [3], [43]. Cyclohexylamine reacts with chlorine to form *N,N*-dichlorocyclohexylamine [44]. For conversion to azomethines and their chemistry, see [45]. *N*-Cyclohexylidenecyclohexylamine reacts with chloramine to give 1-cyclohexyl-3,3-pentamethylenediaziridine, which can be hydrolyzed to give cyclohexylhydrazine [46]. Cyclohexylamine and formaldehyde together react with peracetic acid to give 2-cyclohexyloxaziridine [47]. In addition to using alkyl halides, alkyl sulfates, or alkyl phosphates, cyclohexylamine can be alkylated with an alcohol in the presence of a catalyst, such as aluminum oxide, copper, nickel, cobalt, or platinum (reviewed in [48], [49]), or by the Leuckart – Wallach method [50].

Production. Cyclohexylamine can be produced by catalytic hydrogenation of aniline under pressure. High yields are obtained with nickel or cobalt catalysts treated with basic oxides [51]. Raney cobalt treated with calcium oxide and sodium carbonate gives a cyclohexylamine yield of more than 96 % at 6 MPa and 230 °C [52]. Noble metals also are employed as catalysts [53].

The alternative synthesis from cyclohexanol and ammonia over supported cobalt catalysts [54] is also an important method; calcium silicoaluminates are also suitable catalysts [55]. In this process, cyclohexanol reacts at 20 MPa and 220 °C with at least 3 mol of ammonia in the presence of circulating hydrogen over a fixed-bed catalyst. Using the same continuous procedure, cyclohexanone can be hydrogenated with ammonia under amination conditions [56]; nickel or cobalt catalysts are used for this process, which is carried out at 0.1 – 20 MPa. Cyclohexylamine can also be obtained by reacting phenol with hydrogen and ammonia over a rhodium catalyst [57].

Quality. The purity of the commercial product is above 99.5 % and is determined by gas chromatography; contaminants are ammonia and water.

Storage and Transportation. Cyclohexylamine can be stored and shipped in iron tanks. Nonferrous metals, particularly copper-containing materials, are attacked and are therefore unsuitable. The amine discolors on contact with air and therefore must be kept under nitrogen.

Uses. Cyclohexylamine is used primarily as corrosion inhibitor and vulcanization accelerator. Alone or mixed with other compounds, it has an anticorrosive action [58], for example, when used as an additive in heating oil or in the operation of steam boilers. It is also employed as a salt-forming and amide-forming component in many applications, for example, in the above mentioned vulcanization accelerators (CBS, *N*-cyclohexyl-2-benzothiazylsulfenamide [59]), plasticizers [salts with dodecanethiol and mer-

captobenzothiazole (CMBT)] [60]], emulsifiers (emulsification of active ingredients in water with cyclohexylammonium alkylbenzenesulfonate [61]) and coagulators (salt with acetic acid). Salts of $C_{10}-C_{14}$ fatty acids prevent foam formation in mineral oils [62]. Cyclohexylamine functions as a hardener for epoxy resins and as a catalyst for polyurethanes. Sodium cyclohexylsulfamate and calcium cyclohexylsulfamate (cyclamates) are important artificial sweeteners. In polyamide polymerizations, cyclohexylamine is employed as chain terminator to control the molecular mass. Other applications of cyclohexylamine are for instance in herbicide production. An example is DuPont's Hexazinone [3-cyclohexyl-6-(dimethylamino)-1-methyl-1,3,5-triazine-2,4-(1*H*,3*H*)-dione]. The total market for cyclohexylamine is around 20 000 t/a. Manufacturers include Air Products, BASF, Bayer, and Hoechst Celanese.

***N*-Methylcyclohexylamine** [*100-60-7*], $C_7H_{15}N$, M_r 113.2, is a colorless liquid, *mp* −9 °C, *bp* 150 °C (at 101.3 kPa), d_4^{25} 0.8533, n_D^{20} 1.4551, η 5 mPa · s (at 25 °C).

Vapor pressure

t, °C	20	40	60	80	100	120	140
p, kPa	0.48	1.72	4.68	11.48	24.13	46.26	81.31

Flash point	36.1 °C
Ignition temperature (class T3)	255 °C
Explosion limits in air	2.2 and 10.5 vol % (corresponding to 103 and 494 g/m^3)
Specific heat capacity	2.14 J g^{-1} K^{-1} (at 20 °C) 2.47 J g^{-1} K^{-1} (at 140 °C)

N-Methylcyclohexylamine is infinitely miscible with water, methanol, acetone, toluene, and cyclohexane.

Production. *N*-Methylcyclohexylamine can be prepared by a procedure similar to that used for cyclohexylamine, i.e., by hydrogenation of methylaniline over a supported nickel catalyst [63] or from cyclohexanone and methylamine under hydrogenation conditions [64]. Cyclohexylamine reacts with methanol over copper, zinc, or copper–calcium catalysts [65].

Uses. *N*-Methylcyclohexylamine is used as a component of vulcanization accelerators [66], but the market size is relatively small.

***N,N*-Dimethylcyclohexylamine** [*98-94-2*], cyclohexyldimethylamine, $C_8H_{17}N$, M_r 127.23, is a colorless liquid, *mp* <–50 °C, *bp* 159 °C (at 101.3 kPa), d_4^{25} 0.8467, n_D^{20} 1.4519, η 3 mPa · s (at 25 °C).

Vapor pressure

t, °C	20	40	60	80	100	120	140
p, kPa	0.29	1.05	3.21	8.29	18.13	35.99	63.72

Flash point	38.1 °C
Ignition temperature (class T4)	200 °C
Explosion limits in air	0.79 and 7.0 vol % (corresponding to 41.8 and 370 g/m^3)
Heat of vaporization	285.6 J/g
Specific heat capacity	1.88 J g^{-1}K^{-1} (at 20 °C) 2.51 J g^{-1}K^{-1} (at 140 °C)

The compound is sparingly soluble (1 %) in water, but the solubility of water in dimethylcyclohexylamine is ca. 20 %. *N,N*-Dimethylcyclohexylamine is miscible with conventional organic solvents.

Production. *N,N*-Dimethylcyclohexylamine is produced by hydrogenation of dimethylaniline at 180 °C and 6 MPa [67] or by amination of cyclohexanone under hydrogenation conditions in the presence of dimethylamine [68]. In principle, it could also be obtained from phenol by reaction with dimethylamine, but this route is commercially less attractive.

Uses. *N,N*-Dimethylcyclohexylamine is a catalyst for the production of polyurethane, particularly for making foams, and for this purpose it is used as the free base [69] or as the salt of an organic acid [70]. The curing temperature of baking finishes comprising polyurethane-forming substances can be reduced by 50–80 °C by adding weakly acidic derivatives of the amine [71]. Like pyridine, dimethylcyclohexylamine catalyzes certain reactions and is slightly more efficient than pyridine in the preparation of acid chlorides with thionyl

chloride [72]. It can be used as corrosion inhibitor and as an antioxidant in fuel oils.

***N*-Ethylcyclohexylamine** [*5459-93-8*], $C_8H_{17}N$, M_r 127.2, is a colorless liquid, *mp* −43 °C, *bp* 165 °C (at 101.3 kPa), d_4^{20} 0.846, n_D^{20} 1.4525, η 1.39 mPa · s (at 20 °C).

Vapor pressure

t, °C	20	40	80	120
p, kPa	0.24	0.84	6.13	27.59

Flash point	46 °C
Ignition temperature (class T3)	245 °C
Explosion limit in air	1.2 and 7.6 vol %

N-Ethylcyclohexylamine is only slightly soluble (2.3 %) in water, but the solubility of water in ethylcyclohexylamine is 25 %. The amine is miscible with conventional organic solvents.

Ethylcyclohexylamine is produced by hydrogenation of ethylaniline at 180 °C and 6 MPa [67] or by amination of cyclohexanone under hydrogenation conditions in the presence of ethylamine [68]. The amine is a starting material for the preplant sugar beet, grass, and spinach herbicide cycloate (Zeneca's Ro-Neet), which is obtained by converting *N*-ethylcyclohexylamine into *S*-ethyl-*N*-ethyl-*N*-cyclohexylthiocarbamate. A minor use of *N*-ethylcyclohexylamine is for vulcanization accelerators.

Dicyclohexylamine [*101-83-7*], dodecahydrodiphenylamine, *N,N*-dicyclohexylamine, *N*-cyclohexylcyclohexanamine, perhydrodiphenylamine, $C_{12}H_{23}N$, M_r 181.32, is a colorless liquid, *mp* −0.1 °C, *bp* 256 °C (at 101.3 kPa), *bp* 133 °C (at 2.6 kPa), d_4^{25} 0.9104, n_D^{20} 1.4852.

Flash point	105 °C
Ignition temperature (class T3)	240 °C
Explosion limits in air	0.83 and 4.6 vol % (corresponding to 62 and 350 g/m^3)
Specific heat capacity	1.88 J g^{-1} K^{-1} (at 20 °C) 2.47 J g^{-1} K^{-1} (at 140 °C)

Dicyclohexylamine is sparingly soluble in water (ca. 0.16 % at 28 °C) but is readily soluble in the conventional solvents.

Production. Dicyclohexylamine can be formed as a byproduct in the production of cyclohexylamine from aniline or cyclohexanol/cyclohexanone [73]. When desired as the end product, dicyclohexylamine is obtained by amination of cyclohexanone under hydrogenation conditions [74] or, in higher yield, from cyclohexanone and cyclohexylamine over Pd/C at a hydrogen pressure of 0.4 MPa [75]. Dicyclohexylamine can also be obtained by amination of phenol under hydrogenation conditions, or by the reaction of phenol with aniline over Pd/C at 0.5 MPa under hydrogenation conditions [76].

Uses. Dicyclohexylamine and its salts have good anticorrosion properties in the vapor phase [77]. Paper treated with the nitrite is used as anticorrosion paper. The nitrite also imparts these properties when incorporated into alkyd resins [78]. Like the other cyclohexylamines, dicyclohexylamine is useful as a component of vulcanization accelerators (for instance DCBS, *N,N*-dicyclohexyl-2-benzothiazylsulfenamide, or DCMBT, the salt with 2-mercaptobenzothiazole) and of pesticides. It is also consumed as a processing chemical for antibiotics and as fuel oil additive.

***N*-Methyldicyclohexylamine** [*7560-83-0*], *N,N*-dicyclohexylmethylamine, *N*-cyclohexyl-*N*-methyl-cyclohexanamine, $C_{13}H_{25}N$, M_r 195.35, is a liquid, *bp* 275 °C (at 101.3 kPa), d_4^{25} 0.9207, n_D^{25} 1.4881, η 10.2 mPa · s (at 25 °C), flash point 66 °C.

Vapor pressure

t, °C	63	90	150	190	248
p, kPa	0.133	0.599	2.66	13.33	66.65

N-Methyldicyclohexylamine is sparingly soluble in water and THF but readily soluble in acetone, methanol, toluene, cyclohexane, and chloroform. It is prepared by methylating dicyclohexylamine with dimethyl sulfate or by the Leuckart – Wallach reaction [79] and has uses similar to those of the other cyclohexylamines, e.g., as a urethane foam catalyst.

4,4′-Diaminodicyclohexylmethane [*1761-71-3*], methylene bis(4,4′-cyclohexylamine), bis(4-aminocyclohexyl)methane, 4,4′-methylenebiscyclohexanamine, $C_{13}H_{26}N_2$, M_r 210.36, *mp* 60 – 62 °C (cis,cis), 64 – 65 °C (trans,trans), *bp* 330 – 331 °C (at 101.3 kPa), d_4^{20} 0.96, flash point 153.5 °C, is a water insoluble solid.

The large-volume product 4,4′-diaminodicyclohexylmethane is manufactured by several companies by the catalytic hydrogenation of methylene dianiline. The isomer distribution in the yield is controlled, since the main product from the amine is the isocyanate, which is used in urethane coatings. Other applications include fibers, pigments, films, and epoxy curing agents.

2,2-Bis(4-aminocyclohexyl)propane [*3377-24-0*], isopropylidenedi(cyclohexylamine), $C_{15}H_{30}N_2$, M_r 238.42, *mp* 51 – 53 °C, *bp* 155 – 160 °C (at 0.65 kPa), d_4^{20} 0.99.

2,2-Bis(4-aminocyclohexyl)propane can be obtained by amination of the corresponding bishydroxy compound in the liquid phase under pressure. Product yields of ca. 90 % are obtained over hydrogenation catalysts containing palladium [57], ruthenium [80] or cobalt, manganese, and phosphoric acid [81]. Alternatively, hydrogenation of the condensation product of aniline and acetone, bisaniline A, furnishes the same compound. The industrial product is a mixture of three stereoisomers. Concentration of the trans,trans isomer by treating the isomer mixture with phosphoric acid under reduced pressure at 230 °C or by recrystallization from branched octanes [82] is important because polymerization of the pure isomer gives polyamides of better quality.

Cyclooctylamine [*5452-37-9*], $C_8H_{17}N$, M_r 127.23, is a liquid, *mp* – 48 °C, *bp* 80 °C (at 1.3 kPa), *mp* of hydrochloride 244 – 245 °C, *mp* of picrate 193 – 194 °C, d_4^{20} 0.9280, n_D^{20} 1.4804, flash point 62 °C.

The amine can be produced by the Ritter reaction of cyclooctanol with hydrocyanic acid [83], by reduction of cyclooctanone oxime with sodium and an alcohol [84], by Ritter reaction of cyclooctene with hydrocyanic acid [85], or by catalytic hydrogenation of cyclooctanone under amination conditions [86]. Cyclooctylamine is used as a component of urea herbicides, e.g., cycluron (BASF). Its chemical behavior is analogous to that of other primary amines.

Cyclododecylamine [*1502-03-0*], $C_{12}H_{25}N$, M_r 183.34, *mp* 31 – 32 °C, *bp* 95 – 96 °C (at 0.25 kPa), $n_D^{32.5}$ 1.4849; *mp* of hydrochloride 268 – 270 °C, *mp* of picrate 232 – 234 °C, flash point 121 °C.

Cyclododecylamine is produced by reduction of cyclododecanone oxime with sodium and an alcohol [87], by catalytic reduction of nitrocyclododecane with hydrogen [88], by Ritter reaction of cyclododecene with hydrocyanic acid [89], or by hydrogenation of cyclododecanone under amination conditions [90]. The reaction of cyclododecylamine with propylene oxide leads to a product that can undergo cyclization to give

the fungicide Dodemorph (BASF). The compound behaves chemically as a primary amine.

6. Cyclic Amines

Pyrrolidine [*123-75-1*], tetrahydropyrrole, C_4H_9N, M_r 71.12, is a colorless liquid, *mp* −60 °C, *bp* 87–88 °C (at 101.3 kPa), d_4^{20} 0.8576, n_D^{20} 1.4428, η 1.1 mPa · s (at 20 °C).

Flash point	3 °C
Ignition temperature (class T2)	345 °C
Explosion limits in air	1.6 and 10.6 vol % (corresponding to 47 and 314 g/m^3)
Specific heat capacity	2.20 J g^{-1} K^{-1} (at 21 °C) 2.25 J g^{-1} K^{-1} (at 65 °C) 2.27 J g^{-1} K^{-1} (at 77 °C)
Heat of vaporization	529 J/g (at 0.1 MPa)

Pyrrolidine is infinitely miscible with water and conventional organic solvents such as methanol, acetone, ether, and chloroform. It acts as a lachrymator.

Chemically, pyrrolidine behaves like a secondary amine in every respect. For example, it undergoes Leuckart–Wallach and Mannich reactions and is readily converted into an enamine. In the presence of a catalyst, such as platinum at 360 °C or rhodium at 650 °C [91], pyrrole is formed. In the presence of a copper catalyst, *N*-methylpyrrolidone is converted into *N*-methylpyrrolidine.

Production. Pyrrolidine can be produced from butanediol and ammonia, e.g., over an aluminum thorium oxide catalyst at 300 °C [92] or over a nickel catalyst at 200 °C and 20 MPa under hydrogenation conditions. It can also be produced from THF and ammonia over aluminum oxide at 275–375 °C [93].

Uses. Pyrrolidine is used virtually exclusively for the synthesis of pharmaceuticals, including antibiotics. In addition, it is used for producing vulcanization accelerators.

***N*-Methylpyrrolidine** [*120-94-5*], 1-methylpyrrolidine, $C_5H_{11}N$, M_r 85.15, colorless liquid; *mp* −90 °C, *bp* 80–81 °C (at 101.3 kPa), d_4^{20} 0.7992, n_D^{20} 1.4236, flash point −21 °C.

Piperidine [*110-89-4*], hexahydropyridine, pentamethyleneimine, azacyclohexane, cyclopentimine, cypentil, hexazane, $C_5H_{11}N$, M_r 85.15, derives its name from the alkaloid piperine, the pepper flavoring, in which piperidine is present as piperic acid piperidide.

Piperidine, a colorless liquid, *mp* −10.5 °C, *bp* 106.4 °C (at 101.3 kPa), with a sharp ammonia odor, is hygroscopic and fumes in air; d_4^{20} 0.8613 (the temperature dependence of the density is given in [94]), n_D^{20} 1.4532.

Vapor pressure

t, °C	13.0	25.0	40.0	51.0	67.8	78.8	87.2
p, kPa	2.0	4.0	8.0	13.3	26.7	40.0	53.3

The vapor pressure curve is given in [95]; flash point 3 °C, dissociation constant 1.6×10^{-3} (at 25 °C). Piperidine is infinitely soluble in water, lower alcohols and ketones, ethers, aliphatic and aromatic hydrocarbons, ethyl acetate, and DMF. It forms an azeotrope with water:

p, kPa	100.8	53.3	26.7
bp, °C	93.7	76.9	61.4
Piperidine, mass fraction in %	63.7	68.1	76.0

The preparation of enamines from piperidine takes place particularly smoothly [96], [97], [98]. Unlike open-chain amines, cyclic amines react with aldehydes to give aminals as intermediates [99]. Only pyrrolidine is comparably versatile.

Production. Pyridine obtained from tar distillation is contaminated by sulfur-containing compounds and therefore can be hydrogenated economically only in a two-stage process. The crude pyridine is first hydroraffined over a sulfidic metal catalyst at 280–310 °C and then hydrogenated quantitatively to piperidine at

120 – 160 °C over a Ni – Al_2O_3 catalyst [100]. Sulfur-free pyridine can be hydrogenated over a ruthenium [101] or cobalt catalyst.

The preparation of piperidine by aminolysis of 1,5-pentanediol under hydrogenation conditions at 225 – 260 °C and 20 MPa over a cobalt catalyst has been described [102], but can also be affected with nickel catalysts. A similar preparation from tetrahydrofurfuryl alcohol also has been described [103]. When piperidine is prepared by hydrogenating glutarates [104], glutaric acid [105], or glutaraldehyde [106], the reaction is carried out in the presence of a large excess of ammonia.

Uses. The secondary amine piperidine is highly reactive and is therefore frequently employed as an intermediate for pharmaceuticals [107] and for plant protection agents. It is also used as a vulcanization accelerator in rubber manufacture and as an oil or fuel additive [108].

Piperidine and, in many cases, piperidine acetate are useful catalysts for condensation reactions, e.g., the Knoevenagel reaction [109], aldol condensation [110], and the condensation of a nitroparaffin with an aldehyde [111]. However, for the last of these reactions, diethylamine is the preferred catalyst. The use of piperidine is particularly advisable where the reactants or products are unstable in the presence of stronger bases.

***N*-Methylpiperidine** [*626-67-5*], $C_6H_{13}N$, M_r 99.18, colorless liquid; *mp* – 18 °C, *bp* 106 – 107 °C (at 101.3 kPa), d_4^{20} 0.8157, n_D^{20} 1.4378, flash point 3 °C.

Uses. *N*-Methylpiperidine is used for the production of a growth regulator for cotton plants.

***N*-Ethylpiperidine** [*766-09-6*], $C_7H_{15}N$, M_r 113.20, colorless liquid; *bp* 131 °C (at 101.3 kPa), d_4^{20} 0.8237, n_D^{20} 1.4440, flash point 19 °C.

Uses. *N*-Ethylpiperidine has found use as a catalyst in polycarbonate manufacture.

Hexamethyleneimine [*111-49-9*], HMI, azacycloheptane, hexahydroazepine, homopiperidine, perhydroazepine, $C_6H_{13}N$, M_r 99.18, is a liquid, *mp* – 37 °C, *bp* 139 °C (at 101.3 kPa), d_4^{20} 0.8799, n_D^{20} 1.4658, flash point 30 °C, ignition temperature 255 °C.

Hexamethyleneimine and water form a 1/1 azeotrope that boils at 95 – 95.5 °C. The hexamethyleneimine – water solubility curve is given in [112]. The chemical behavior of hexamethyleneimine is determined entirely by the secondary amino group.

Production. Hexamethyleneimine is produced in 84 % yield by heating hexamethylenediamine at 350 °C in a stream of hydrogen. The catalyst, ammonium vanadate on activated alumina, is prereduced with hydrogen at 500 °C [113]. Residues from the industrial distillation of hexamethylenediamine can be converted into hexamethyleneimine over aluminum silicate or aluminum oxide in a stream of nitrogen [114]. For the preparation from caprolactam, see [115]. Hexamethyleneimine can be prepared by dimerizing acrolein, reducing the product to 2-hydroxymethyltetrahydropyran, expanding the ring to give oxepane, followed by treatment with ammonia over aluminum oxide at 350 °C [116].

Uses. The most important use is the conversion of hexamethyleneimine into *S*-ethylhexahydro-1*H*-azepine-1-carbothioate, the selective rice herbicide Molinate (C_2H_5S–CO–NC_6H_{12}, Zeneca). Minor amounts of hexamethyleneimine are used for the production of rubber vulcanization accelerators, resins, pharmaceuticals, and textile auxiliaries; numerous patents describe the anticorrosive action of hexamethyleneimine and its derivatives.

Morpholine [*110-91-8*], tetrahydro-2*H*-1,4-oxazine, diethylene oximide, diethylenimide oxide, 1-oxa-4-azacyclohexane, C_4H_9NO, M_r 87.12, is a colorless hygroscopic liquid; *mp*

$-5\,°C$, *bp* 128.2 °C (at 101.3 kPa), d_4^{20} 1.007, n_D^{20} 1.4542, η 2.3 mPa · s (at 20 °C).

Vapor pressure

t, °C	10	20	40	60	80	100	120
p, kPa	0.57	1.1	3.2	8.3	20.5	40.9	81.8

Critical pressure	5.302 MPa
Critical temperature	344 °C
Flash point	43 °C
Ignition temperature	275 °C
Explosion limits in air	1.8 vol % and 15.2 vol %
Specific heat capacity	1.2 J g^{-1}K^{-1} (at 25 °C) 2.15 J g^{-1}K^{-1} (at 100 °C)
Heat of vaporization	505 J/g (at 25 °C) 425 J/g (at 128 °C)

Morpholine is infinitely miscible with water and conventional solvents such as methanol, acetone, benzene, and glycol. The mixture consisting of 88 % morpholine and 12 % water has a freezing point below $-50\,°C$ and a viscosity of 7.45 mPa · s at 20 °C.

Chemically, morpholine behaves as a secondary amine in every respect. It forms complexes with many cations. In addition to the Leuckart – Wallach and Mannich reactions, the conversion to enamines has become important [96], [97]. Morpholine, pyrrolidine, and piperidine are preferred to the open-chain amines for these reactions because they react faster with the carbonyl component.

Production. Morpholine can be obtained from diethanolamine by cyclization with sulfuric acid or via diethanolamine hydrochloride [117] or from di(2-chloroethyl) ether and ammonia [118]. Industrially more important is the amination of diglycol under hydrogen pressure and over a cobalt or nickel catalyst [42], [119]. Other catalysts are described in [120]. An important byproduct frequently obtained is 2-(2-aminoethoxy)ethanol, which is the result of simple amination without subsequent cyclization; after separation of morpholine, this compound can be recycled to the synthesis reactor.

Quality and Storage. When produced from diglycol, commercial morpholine is more than 99 % pure; the main impurities are *N*-ethylmorpholine and ethylenediamine. Morpholine can be stored for an unlimited time in iron containers if it is protected from atmospheric moisture and carbon dioxide. Copper, zinc, and their alloys are unstable towards morpholine.

Uses. Morpholine is an intermediate for a large number of pharmaceuticals, crop protection agents, dyes, and optical brighteners. An important use is the conversion to vulcanization accelerators or sulfur donors, which are based on 2-mercaptobenzothiazole, dithiocarbamic acid, thiuram polysulfides, or sulfenamides, e.g., MBS [2-(4-morpholinylmercapto)benzothiazole], DTDM (4,4′-dithiodimorpholine), and MBSS (4-morpholinyl-2-benzothiazyl disulfide). Salts of morpholine with long-chain fatty acids, such as oleic or stearic acid, have waxlike properties and are used as emulsifiers.

Because water and morpholine have similar volatilities and the latter is an anticorrosion agent, it is useful in steam cycles [121], aqueous hydraulic liquids [122], and similar systems. Up to 550 °C, no substantial loss occurs as a result of decomposition.

An aqueous solution of morpholine (2 M) can be used for removing CO_2, H_2S, or HCN from gases [123]. In the extraction of aromatic compounds from hydrocarbon mixtures, morpholine is highly selective [124].

Morpholine Derivatives. *N*-Methylmorpholine and *N*-ethylmorpholine are used as catalysts for the production of polyurethane foams. *N*-Formylmorpholine is used as a selective solvent for the extraction of high-purity aromatic compounds in the Formex process (Snamprogetti).

N-Methylmorpholine [*109-02-4*], 4-methyl-1-oxa-4-azacyclohexane, $C_5H_{11}NO$, M_r 101.15, *mp* $-65\,°C$, *bp* 114 °C (at 101.3 kPa), d_4^{20} 0.919, n_D^{20} 1.4347, η 0.90 mPa · s (at 20 °C), flash point 13 °C.

Methylmorpholine can be obtained from diethylene glycol and methylamine or by reacting morpholine with formaldehyde to give *N*-hydroxymethylmorpholine and reducing the product with excess formaldehyde [125], formic acid [126], or hydrogen over cobalt or manganese catalysts under pressure [127]. Another important reaction is the alkylation of morpho-

line with methanol at a total pressure above 3.5 MPa and a hydrogen partial pressure above 1 MPa [128].

Alkylmorpholines are also obtained by cyclization of bis(2-chloroethyl) ether with an amine [129] or of diethylene glycol with an amine in the presence of hydrogen and a hydrogenation catalyst [130].

N-Ethylmorpholine [*100-74-3*], $C_6H_{13}NO$, M_r 115.18, *mp* −63 °C, *bp* 134–137.5 °C (at 101.3 kPa), d_4^{20} 0.913, n_D^{20} 1.4415, η 1.05 mPa · s (at 20 °C), flash point 27 °C, is miscible with water.

N-Formylmorpholine [*4394-85-8*], 4-morpholinecarbaldehyde, $C_5H_9NO_2$, M_r 115.13, *mp* 20–21 °C (anhydrous), 9 °C (5 % water), –3 °C (10 % water), *bp* 244 °C (anhydrous), 172 °C (2 % water), 151 °C (5 % water), 132 °C (8 % water) (all at 101.3 kPa), d_4^{20} 1.1268, n_D^{20} 1.4835, flash point 124 °C, is hygroscopic.

N-(2-Hydroxyethyl)morpholine [*622-40-2*], 4-(2-hydroxyethyl)morpholine, 4-morpholinoethanol, $C_6H_{13}NO_2$, M_r 131.17, *mp* −1 °C, *bp* 227 °C (at 100.9 kPa), d_4^{20} 1.0733, n_D^{20} 1.4760, flash point 99 °C, is used as an intermediate for pharmaceuticals.

N-(2-Aminoethyl)morpholine [*2038-03-1*], 2-morpholinoethylamine, 4-(2-aminoethyl)-morpholine, $C_6H_{14}N_2O$, M_r 130.19, *mp* 24 °C, *bp* 205 °C (at 101.3 kPa), d_4^{20} 1.001, n_D^{20} 1.4755, flash point 175 °C, is used as an intermediate for pharmaceuticals.

Piperazine [*110-85-0*], 1,4-diethylenediamine, hexahydropyrazine, dispermine, hexahydro-1,4-diazine, $C_4H_{10}N_2$, M_r 86.14, forms strongly hygroscopic, colorless lamellar crystals with a typical amine odor, *mp* 109.6 °C, *bp* 148 °C (at 101.3 kPa), *mp* of the hexahydrate 42.0 °C.

Vapor pressure

t, °C	110.8	121.7	125	140.6
p, kPa	30.3	44.6	49.6	79.7

Flash point	98 °C
Ignition temperature	340 °C
Explosion limits in air	3.93 kPa and 12.0 kPa (corresponding to 139 g/m^3 and 430 g/m^3)

These are the saturated vapor pressures above piperazine at 64.0 °C and 90.5 °C.

Specific heat capacity	2.94 J g^{-1} K^{-1} (at 130 °C) 2.99 J g^{-1} K^{-1} (at 140 °C)
Heat of vaporization	47.3 J/g

Piperazine is readily soluble in water, methanol, and ethanol but only slightly soluble in diethyl ether, benzene, and heptane. Piperazine has the chemical properties of a secondary amine. Vapor-phase dehydrogenation over copper chromite or palladium gives pyrazine.

Production. Piperazine is obtained as a byproduct in the production of ethylenediamine, in particular when ethanolamine is used as starting material [131]. If ethanolamine reacts with ammonia at 150–220 °C and 10–25 MPa, piperazine can be distilled from the reaction mixture, which also contains unreacted ethanolamine, ethylenediamine, diethylenetriamine, aminoethylethanolamine, and polyamines.

Piperazine is obtained with a purity of 99 %, and can be converted to flakes, even after conversion to the hexahydrate. Frequently, it is transported as an approximately 65 % aqueous solution, which has a low melting point of about 45 °C and hence corresponds roughly to an eutectic mixture. The purity is determined in most cases by gas chromatography. If it can be assumed that organic impurities are absent, the purity can be determined titrimetrically (HCl or $HClO_4$) in aqueous solution.

Storage. Since piperazine is corrosive, the flakes are stored in barrels lined with a polyethylene sack. To avoid yellowing, the barrels should be air tight and not exposed to direct sunlight.

The aqueous solution is stored at 50 – 60 °C in insulated iron tanks that can be heated.

Uses. Piperazine, in the form of the hexahydrate or as salts, is used as an anthelmintic in human and veterinary medicine. Furthermore, the piperazine ring is a constituent of a large number of other pharmaceuticals. It is also an intermediate for dyes, corrosion inhibitors, rubber vulcanization accelerators, insecticides, and surfactants.

The production of polyamides from piperazine and aliphatic dicarboxylic acids has long been known [132], but has remained unimportant. The polymers so formed have a heat resistance superior to that of conventional polyamides but require the use of stabilizers [133].

The use of 1,4-bis(1-aziridinylcarbonyl)-piperazine or 1,4-bis(chloroacetyl)piperazine for curing gelatine for photographic purposes was proposed [134].

***N*-Methylpiperazine** [*109-01-3*], 1-methylpiperazine, $C_5H_{12}N_2$, M_r 100.16, colorless hygroscopic liquid, *mp* – 6 °C, *bp* 138 °C (at 101.3 kPa), d_4^{20} 0.9021, n_D^{20} 1.4658, flash point 42 °C.

***N*-Ethylpiperazine** [*5308-25-8*], 1-ethylpiperazine, $C_6H_{14}N_2$, M_r 114.19, colorless liquid, *mp* – 60 °C, *bp* 157 °C (at 101.3 kPa), d_4^{20} 0.8989, n_D^{20} 1.4690, flash point 47 °C.

***N,N′*-Dimethylpiperazine** [*106-58-1*], 1,4-dimethylpiperazine, $C_6H_{14}N_2$, M_r 114.19, colorless liquid, *mp* – 1 °C, *bp* 131 – 132 °C (at 101 kPa), d_4^{20} 0.8509, n_D^{20} 1.4463, flash point 18 °C, can be used as catalyst for polyurethane foams and as an intermediate for cationic surfactants. It is obtained from piperazine and methanol or formaldehyde under aminating conditions.

***N*-(2-Aminoethyl)piperazine** [*140-31-8*], AEP, 1-(2-aminoethyl)piperazine, 2-piperazin-1-ylethylamine, $C_6H_{15}N_3$, M_r 129.21, colorless liquid, *mp* – 19 °C, *bp* 218 – 222 °C (at 101.3 kPa), d_4^{20} 0.9842, n_D^{20} 1.5000, flash point 93 °C, η 15 mPa · s (at 20 °C) is corrosive, toxic, and hygroscopic. AEP is a byproduct of ethylenediamine production and is used as a hardener for epoxy resins, as an urethane catalyst, and also acts as a corrosion inhibitor [135]. It is also an intermediate for dyes, surfactants and various pharmaceuticals.

***N*-(2-Hydroxyethyl)piperazine** [*103-76-4*], HEP, 1-(2-hydroxyethyl)piperazine, 1-piperazineethanol, $C_6H_{14}N_2O$, M_r 130.19, *mp* – 10 °C, *bp* 246 °C (at 101.3 kPa), d_4^{20} 1.0595, n_D^{20} 1.5058, flash point 135 °C. HEP is obtained during ethyleneamine production and used for corrosion inhibitors, pharmaceuticals, surfactants, and synthetic fibers.

Triethylenediamine [*280-57-9*], TEDA, 1,4-diazabicyclo[2.2.2]octane, Dabco, $C_6H_{12}N_2$, M_r 112.17, is a highly symmetrical molecule with a cage structure. The colorless extremely hygroscopic crystals melt at 159.8 °C; *bp* 174 °C, pK_{a1} 2.95, pK_{a2} 8.60, flash point 50 °C.

Triethylenediamine reacts virtually quantitatively with bromine to give a 1/1 adduct. With alkyl halides it forms quaternary salts, even in nonpolar solvents. Apart from its highly nucle-

ophilic nature, triethylenediamine exhibits catalytic activity in base-catalyzed reactions.

Production. Triethylenediamine can be produced from ethylenediamine or ethanolamine [136], diethanolamine [137], or diethylenetriamine [138] with a variety of different catalysts. All processes give only moderate yields. For example, in the presence of a catalyst consisting of 86 % silicon dioxide and 12 % aluminum oxide at 360 °C and atmospheric pressure, diethylenetriamine gives about equal amounts of piperazine, alkylpiperazines, pyrazines, and ethylenediamine and homologues in addition to the bicyclic compound. Fractional distillation, subsequent recrystallization from acetone, and washing with petroleum ether give 95 % pure triethylenediamine; sublimation gives a 98 % pure product. Processes starting from piperazine derivatives (*N*-hydroxyethylpiperazine, *N,N′*-bishydroxyethylpiperazine or *N*-aminoethylpiperazine) are described in [137], [139]. Dealuminated or untreated ZSM-5 zeolites are claimed to produce TEDA from various precursors, including ethanolamine and piperazine [140]. Compared to the amorphous catalysts, the zeolite catalysts have the advantage of shape selectivity.

Uses. The only important industrial use of triethylenediamine is as a hardener for polyurethane foams [141]. However, more effective aza- and diazabicyclooctane derivatives intended for the same purpose have been the subject of patent applications [142].

Hexamethylenetetramine [*100-97-0*], HMTA, hexamine, methenamine, 1,3,5,7-tetraazaadamantane, 1,3,5,7-tetraazatricyclo[3.3.1.1(3,7)]decane, $C_6H_{12}N_4$, M_r 140.19, is a highly symmetrical molecule with an adamantane structure. Trade names: Urotropin, Formin, Aminoform. It crystallizes from ethanol as colorless, hygroscopic rhombododecahedra.

At reduced pressure (2 kPa), hexamethylenetetramine sublimes at 230 – 270 °C, virtually without decomposition, $mp > 270$ °C (decomp.), ϱ 1.3394 g/cm^3 (at 22 °C), enthalpy of formation 124.1 ± 0.75 kJ/mol. For further thermodynamic data, see [143]. For the IR spectrum, see [144]. The vapor pressure between 20 and 280 °C can be calculated from the formula $\log(p/\text{kPa}) = -524.8/(T/\text{K}) + 1.334$ [145]. Flash point 250 °C.

At 12 °C, 81.3 g of hexamethylenetetramine dissolves in 100 g of water; the solubility decreases slightly with increasing temperature. The dissociation constant is 1.4×10^{-9} (temperature not given). The solubility of hexamethylenetetramine in 100 g of various solvents at 20 °C is as follows: 13.4 g in chloroform, 7.25 g in methanol, 2.89 g in absolute ethanol, 0.65 g in acetone, 0.23 g in benzene, 0.14 g in xylene, 0.06 g in ether, and near zero in petroleum ether.

Hexamethylenetetramine gives a monobasic reaction, but with strong acids it is dibasic. The equilibrium $C_6H_{12}N_4 + 6\,H_2O \rightleftharpoons 6\,CH_2O + 4\,NH_3$ in aqueous solution permits the use of hexamethylenetetramine as a formaldehyde or ammonia donor. Thermolysis leads to hydrocyanic acid in a yield of 73 % at 800 °C, and 92 % at 1200 °C [146]. Nitration gives 1,2,3-trinitro-1,2,3-triazine, which is an important explosive (hexogen, cyclonite, RDX). The intact tricyclic structure can be alkylated and arylated at the nitrogen atom and halogenated at the carbon atom. It undergoes a large number of addition reactions: adduct formation with phosgene, disulfur dichloride, and many inorganic salts.

Production. Formaldehyde and ammonia can be converted into hexamethylenetetramine in the gas phase, in aqueous solution, or in a suspension in an inert solvent, although the most important of these procedures is that carried out in water. The usual process gives a pure product in yields near 90 % and includes an economical drying step.

If aqueous solutions of ammonia (27 %) and formaldehyde (30 %) react continuously at up to 95 °C in a V4A stainless steel tubular reactor, it is necessary to dewater a 14 % solution of hexamethylenetetramine [147]. If formaldehyde and ammonia are reacted in the vapor phase, the product is precipitated with cold water [148] or is discharged with an aqueous solution of hexamethylenetetramine [149].

The heat of reaction in aqueous solution is 230 kJ/mol, and in the vapor phase 745 kJ/mol. Therefore, the presence of a minimum amount of water is desirable. In this method [150], ammonia gas and formaldehyde gas are passed

continuously into the boiling reaction solution. The boiling point is brought to 50 – 70 °C. The heat of hydration and heat of reaction vaporize the water of condensation. The hexamethylenetetramine is removed in crystalline form or as a concentrated solution.

In another method, ammonia gas and formaldehyde solution react at pH 7.5 – 8 and 50 – 90 °C, and the product is granulated by spray drying in a hot inert gas stream (220 – 250 °C), or by spraying it onto hexamethylenetetramine particles in a fluidized bed in an air stream at 80 – 115 °C [151].

Quality. As a rule, the industrial product is 99 % pure. The compound is purified by stepwise crystallization (see [152]). The addition of paraffin, benzoic acid, acid amides, or diatomaceous earth gives free-flowing products [153].

Uses. Hexamethylenetetramine can be used as an ammonia or formaldehyde donor, for example, in the production of phenol resins, urea – formaldehyde resins and in fuel tablets. Further uses are the production of the high explosives hexogen and octogen, vulcanization accelerators, and anticorrosion agents. Proposed uses relate to the activation of chlorites as bleaches [154] and the preservation of foodstuffs [155], paints, finishes, and latexes [156], and as antibacterial agent for the urinary tract.

7. Fatty Amines

Straight-chain primary, secondary, and tertiary amines with chain lengths between 8 and 24 carbon atoms are commonly known as fatty amines. This group of compounds also includes derivatives such as the *N*-alkyl-1,3-propanediamines. Of commercial importance are fatty amine mixtures, such as coco amine, tallow amine, hydrogenated tallow amine, oleylamine, and soya amine, which are derived from naturally occurring fatty acids. More recently, alkylamines of similar structure were produced from synthetic feedstocks such as olefins or paraffins, and these also are called fatty amines (β-amines, branched chain amines, aminoalkanols). Only partly covered are fatty amine ethoxylates, fatty alkyl quaternary ammonium salts, alkyl betaines and fatty amine oxides, although all of these are fatty amine derivatives.

7.1. Properties

Physical Properties. Table 2 lists typical compositions of fatty amine mixtures. The properties of these can be varied to some extent by blending chain lengths with the desired physical characteristics. Fatty acids are also available in fractionated form and thus narrower ranges of fatty amines may be produced.

Solubilities of selected fatty amines in polar and nonpolar organic solvents are given in Table 3. Only the short-chain fatty amines with 8 – 10 C atoms per alkyl chain are of limited solubility in water.

Table 3. Solubility (g per 100 mL at 30 °C) of fatty amines in organic solvents [158]

	2-Propanol	Hexane

Vapor pressures at ambient temperature are generally very low and decrease from 26.5 Pa for dodecylamine to 2.7×10^{-2} Pa (0.27×10^{-3} mbar) for eicosylamine. Some physical properties of pure compounds and commercial mixtures are given in Tables 4 and 5.

The oscillation of *melting points* between the series of odd-chain and even-chain homologues is shown in Figure 2. This effect disappears in derivatives of primary fatty amines.

Almost all amines derived from natural sources have an even number of carbon atoms. Diamines and 2-(alkylimino)diethanols [*N,N*-bis(2-hydroxyethyl)alkylamines] are low-melting pasty solids. Unsaturation decreases the melting points of the amines relative to the fully saturated compounds. Fatty amines and their derivatives are cationic surfactants (→ Surfactants) and show strong substantivity to the negatively charged surface of most solids, e.g., cotton, minerals, and metals, and thus change the physical properties of the substrates [163], [164].

Chemical Properties. Fatty amines, like short-chain amines, are stronger bases than am-

monia. Their ionization constants [165] do not change significantly with chain length (see Table 6), and their reactions are similar to those known from the lower homologues.

Table 6. pK_b Values of amines in water at 25 °C *

R	RNH_2	R_2NH	R_3N
Methyl	3.38	3.29	4.24
Ethyl	3.37	3.02	
Octyl	3.35	3.00	
Octadecyl	3.40	3.00	

* The pK_b of NH_3 in water at 25 °C is 4.79.

The following are industrially important reactions:

1) *Salt formation* with inorganic and organic acids. The hydrochlorides are slightly more soluble and the acetates considerably more soluble in water than the free amines. Acetates and salts of higher fatty acids are readily soluble in organic solvents [158]. The melting points of the salts are higher than those of the free amines.
2) *Conversion* into *N*-alkyl carboxamides with carboxylic acids or their derivatives.
3) Reaction with *carbon dioxide* to give carbamates, which are formed as contaminants in amines exposed to air.
4) *Alkylation* with excess of strong nucleophiles, such as methyl chloride, benzyl chloride, or dimethyl sulfate, leading eventually to quaternary ammonium compounds. This reaction is normally carried out in aqueous alcohol as the solvent and in the presence of alkali as the proton acceptor [166], [167].
5) *Oxyalkylation*with ethylene oxide, a more selective reaction than alkylation. The uncatalyzed reaction with primary amines at 150 – 200 °C yields almost exclusively 2-(alkylimino)diethanols (*N,N*-bis(2-hydroxyethyl) fatty amines). Base catalysis even at temperatures as low as 100 °C leads to bis(polyoxyethyl) amines [168]. Under mild conditions (80 °C, 350 Pa) and in the presence of water or acids, secondary and tertiary amines react readily with ethylene oxide to form the corresponding bis- or mono(2-hydroxyethyl) quaternary ammonium salts [169–171]. Long-chain epoxides undergo a similar reaction [172], but products from ethylene and propylene oxide are the only important commercial products.
6) Reaction of fatty amines with *halogenated carboxylic acids* or with *lactones* to give amphoteric compounds (betaines).
7) *Michael addition* to activated double bonds. For example, the important 1,3-propanediamines are synthesized by the reaction of a primary fatty amine with acrylonitrile followed by hydrogenation of the intermediate 2-(alkylimino)ethanenitrile [173].
8) *Mannich reactions* with formaldehyde and nucleophiles, such as aldehydes, nitroparaffins, or phenols, to form polyfunctional derivatives [174–176].
9) *Reaction with phosgene* to form isocyanates and ureas.
10) *Oxidation* by hydrogen peroxide, peroxoacids, or ozone to give amine oxides. Industrially, oxidation of tertiary amines to amine oxides by hydrogen peroxide is very impotant since the products find use as surfactants.

7.2. Production

Fatty amines can be produced from natural fats and oils or from synthetic raw materials [177].

Production from Fatty Nitriles. The most important source of fatty amines is still fatty nitriles, which are themselves formed from fatty carboxylic acids and ammonia over optional dehydrating catalysts (Al_2O_3, SiO_2, ZnO, bauxite, or salts of Ti, Fe, Mn, or Co) in batch liquid-phase reactors or continuous liquid- and vapor-phase reactors at 160 – 430 °C and 0.03 – 0.7 MPa. The principal raw materials are coconut oil, palm kernel oil, and tallow.

Depending on the process, the nitriles are purified by distillation or used as such. The fatty acid feedstocks may be fractionated beforehand as well. Hydrogenation of nitriles can lead to all three types of amine, depending on reaction conditions. Hydrogenation may be batch or continuous and is sensitive to catalyst poisons from the natural feedstock.

Primary amines are formed by hydrogenation of fatty nitriles, typically at 80 – 140 °C and 1 – 4 MPa, over nickel or cobalt catalysts. Raney cobalt or copper chromite catalysts are

used to obtain *unsaturated amines* [178–180]. To avoid formation of secondary amines, ammonia is commonly used as a suppressant; a solvent may also be used.

Secondary Amines. If ammonia is continuously or periodically vented from the reactor and temperatures of 150 – 210 °C and pressures of 5 – 20 MPa are maintained, saturated and unsaturated secondary amines can be obtained in yields of > 90 % [181], [182]. Catalysts mainly used are nickel, cobalt, and copper chromite.

Tertiary Amines. Symmetrical trialkylamines are obtained similarly to the secondary amines, but usually mixtures of primary, secondary, and tertiary amines result. Tertiary amines may also be produced from nitriles via the imine RCH=NH and Schiff base RCH=N–CH_2R by using supported nickel catalysts at 230 °C and 0.7 MPa hydrogen partial pressure [183].

More important are the *N*-alkyl-*N*-methylalkylamines and the *N,N*-dimethylalkylamines, which can be synthesized by the Leuckart reaction of primary or secondary amines [184], [185]:

$$R_2NH + CH_2O + HCOOH \longrightarrow R_2NCH_3 + CO_2 + H_2O$$

$$RNH_2 + 2\,CH_2O + 2\,HCOOH \longrightarrow RN(CH_3)_2 + 2\,CO_2 + 2\,H_2O$$

Industrially, the reduction of the formaldehyde may be achieved with hydrogen and a nickel catalyst, e.g.:

$$RNH_2 + 2\,CH_2O + 2\,H_2 \longrightarrow RN(CH_3)_2 + 2\,H_2O$$

N,N-dimethylalkylamines can also be produced from fatty nitriles and dimethylamine [186]. Both types of methyl-substituted tertiary amines are accessible also from primary alcohols [187], [188], and this route is used almost exclusively.

Efforts to use methanol or hexamethylenetetramine to methylate the nitriles with different catalysts to obtain *N,N*-dimethylalkylamines or *N*-methyldialkylamines are descibed in [189].

Production from Alcohols or Carbonyl Compounds. Fatty amines are produced by reductive alkylation of ammonia or substituted amines with primary linear alcohols ($C_8 - C_{18}$) at 90 – 190 °C under low pressure (atmospheric up to 0.7 MPa) in the presence of a Raney nickel catalyst. If water is continuously removed from the reactor, only secondary and tertiary amines are obtained [190–192]. Similarly, aldehydes can be converted into primary amines by reductive amination at 110 – 120 °C and 1.5 MPa with rare earth-promoted cobalt catalysts [193]. Oxo aldehydes react with methylamine to form imines, which are then hydrogenated to give *N*-methylalkylamines at 115 °C and 3 MPa with a Raney nickel catalyst [194]. Similarly, both alcohols and aldehydes can be converted into *N,N*-dimethyl tertiary amines with dimethylamine. Alcohols are converted into amines at 230 °C at atmospheric pressure with copper chromite catalysts, whereas fatty aldehydes require noble metal, copper chelate, or copper carboxylate catalysts [195–198].

The widely used fatty alkyl dimethylamines are nowadays almost exclusively produced from long-chain natural, oxo, or Ziegler fatty alcohols ($C_{12} - C_{18}$). Conversion is achieved by reacting dimethylamine with the fatty alcohol at elevated temperatures and pressures with copper, copper chromite, or nickel catalysts. Alternatively, the fatty alcohol can initially be converted to the primary fatty amine by using ammonia and a nickel catalyst and subsequently treated with formaldehyde as described above. Some other two-stage processes starting from fatty alcohols and with sodium alkyl sulfates or chlorides as intermediates have been described, but direct conversion with dimethylamine is the most attractive.

Production from Olefins. α-Olefins can be converted to 1-bromoalkanes by radical addition (anti-Markovnikov) of hydrogen bromide [199]. Reaction with ammonia furnishes primary fatty amines, and using dimethylamine results in tertiary fatty amines. A higher amount of branched chain isomers is likely for the α-olefin route as compared with the alcohol route.

Under hydrocarbonylation conditions, α-olefins and dimethylamine form *N,N*-dimethylalkylamines directly if highly selective noble metal catalysts are used [200]. Use of the less specific tributylphosphinecobalt catalysts leads to mixtures of amines and alcohols [201].

In a *Ritter reaction*, α-olefins react with hydrogen cyanide or acetonitrile in concentrated sulfuric acid or aqueous hydrogen fluoride, via the intermediate 2-acylaminoalkane, to

give branched alkyl primary amines (β-amines). The reaction is not specific, and positional isomers are also formed [202], [203].

Aluminum alkoxides, as formed in the Ziegler process, can be used to convert secondary amines into tertiary amines [204].

Production from Alkane Derivatives. *Nitroalkanes* with a statistical distribution of nitro groups can be hydrogenated over Pd/C at 190 °C and 3.9 MPa to form secondary alkyl primary amines in yields of up to 93 % [205]. Nickel catalysts can also be used. Selectively *chlorinated alkanes* react with dimethylamine to yield up to 65 % terminal tertiary amine [206].

Production from Other Starting Materials. Glycerides and methyl esters of fatty acids can be converted into fatty nitriles at 220 – 300 °C provided ammonia is vented rapidly. Yields of nitrile and glycerine in excess of 80 % were reported with zinc carboxylate or aryl sulfate catalysts [207]. Under hydrogenation conditions over Zn – Al catalysts at high pressures (10 – 30 MPa) and temperatures (200 – 350 °C), coconut glycerides can be converted into primary coco amine. Glycerine, however, decomposes completely under these conditions [208].

Primary fatty amides can be converted in high yields into odd-chain primary amines by Hofmann degradation of the chloroamide intermediate [209]:

These fatty amines have an uneven number of carbon atoms and are hence distinct from the more common primary amines from the nitrile route.

***N*-Alkyl-1,3-propanediamines.** These so called fatty diamines are obtained by acrylonitrile addition to fatty amines followed by hydrogenation in the presence of ammonia:

$$RNH_2 + CH_2{=}CHCN \longrightarrow RNH(CH_2)_2CN$$

$$RNH(CH_2)_2CN + 2\,H_2 \longrightarrow RNH(CH_2)_3NH_2$$

Acrylonitrile addition may be catalyzed by the presence of methanol and is conducted at temperatures between 30 and 90 °C. Hydrogenation is performed under the same conditions as for the fatty nitrile hydrogenations above. Polyamines may also be obtained similarly.

7.3. Analysis and Quality Control

Because of their relatively high basicity, fatty amines can be titrated easily with acids. Most of the amines are insoluble in water; therefore, organic solvents, such as isopropyl alcohol, are commonly used. End points are determined colorimetrically (bromophenol blue) or potentiometrically. In the second case, perchloric acid and glacial acetic acid are preferred as titrant and solvent, respectively.

Industrial mixtures of amines normally contain up to 90 % of the main compound. These mixtures are analyzed by stepwise titrations with acid. The total basicity is determined first. Primary amines then are removed with salicylaldehyde, and primary and secondary amines can be removed with phenylisothiocyanate or acetic acid, so that the remaining free amine can be titrated with acid. Unsaturated amines are determined by means of the iodine number. Because amine groups also consume iodine, the original Wijs method must be slightly modified by using acetic acid as the solvent. The resulting amine salt absorbs the halide at a much slower rate than the double bonds.

Quaternary ammonium compounds usually are determined by solvent partition titration with anionic surfactants or sodium tetraphenylboron [210]. Iodine numbers of quaternary ammonium compounds are obtained in sodium lauryl sulfate containing chloroform to prevent the free iodine from being retained by the nonaqueous phase. A summary of approved wet chemical test methods (AOCS, ASTM) is given in [211].

Chain-length distribution and hydrocarbon content of fatty amines are determined by gas chromatography [212–216]; nitrile and amide impurities are determined by IR spectroscopy [217], [218].

More recently, NMR spectroscopy has been used for determination of quaternary ammonium compounds in the presence of free amines [219] and also for establishing the relative amounts of

primary, secondary, and tertiary amines in mixtures [220].

Fatty amines can be stored in carbon steel containers; aluminum, copper or their alloys are to be avoided. Quaternary amines are more corrosive and thus require lined drums or stainless steel. With water hydrates are formed by primary and secondary amines and carbamates with CO_2.

7.4. Uses

Fabric Softeners. By far the largest use of fatty amines and in particular their quaternary derivatives used to be in fabric softening. Prior to the early 1950s, fabric softeners were not needed because most detergents were based on tallow-derived soap formulations and some of the active detergent remained on the textile and resulted in a softer dried fabric. However, the advent of synthetic detergents created the market for fabric softeners in home care and institutional laundries.

Most of these softeners are used in *rinse cycles* where a 3 – 8 % formulated aqueous dispersion is added leaving 0.1 – 0.2 % active quaternary ammonium compound on the surface of the clothes. Since the 1980s, concentrates have been developed, which contain up to 50 % active ingredients. In another usage, a quaternary fabric softener is applied to a substrate, such as paper, to woven or nonwoven cloth, or to a foam and then added to the *drying cycle*. The formulation contains a quaternary ammonium compound and a transfer agent that allows the active ingredient to be transferred to the cloth during the drying cycle. The prevention of static buildup is actually more important than the softening action in this application. A third area of application are *wash cycle* softeners, in which quaternaries are combined with other detergents to achieve both cleaning and softening.

The fatty quaternary ammonium compounds used were formerly mainly dimethyl dihydrogenated tallow ammonium chloride, but this compound was replaced in many countries by other surfactants because of its lack of biodegradability and potential aquatic toxicity. Nowadays the most widely used quaternaries are ester quats, which are not derived from fatty amines but from fatty acids, alcoholamines (e.g., triethanolamine), and methylating agents.

Amine ethoxylates, mainly derived from primary tallow, hydrogenated tallow and coconut amines, are also used in large amounts for textiles.

Flotation. One of the first commercial uses of primary fatty amines was in the beneficiation of potash [221]. In this process, fatty amine salts adhere to the surface of potassium chloride, allowing it to be removed by froth flotation and leaving the sodium chloride in the tailings. The technique spread to other mineral beneficiation processes [222], the most important of which are phosphate rock, precious metals, lead, zinc, copper, molybdenum, tin, fluorspar, feldspar, magnesite, limestone, mica, manganese, silica, and coal. In general, any negatively charged surface can be removed from a system with an amine salt. Ore flotation accounts for the largest direct use of primary fatty amines. Other fatty amines used for mining are quaternary componds and some diamines, but these are less important.

Corrosion Inhibition. Large quantities of amines are used in corrosion inhibition. The cationic amino group adheres to the surface of metals and prevents attack by corrosive liquids and gases. Primary amines and *N*-alkyl-1,3-propanediamines are used most frequently for this purpose. The amines may be neutralized with oleic, naphthenic, and acetic acids to adjust their solubility. A typical oil-soluble inhibitor formulation contains *N*-tallow-1,3-propanediamine dioleate.

Asphalt Emulsification. The cationic nature of fatty amines makes them useful as emulsifiers for asphalt. Primary amines, diamines, polyamines, alkoxylated amines, and fatty quaternary ammonium compounds can be used in this application. The formulation used depends on the properties of the emulsion desired. The cationic emulsion can be rapid, medium, or slow set. In all cases a cationic emulsifier is used at a low concentration (0.2 – 2.0 wt % of the emulsion). When the cationic emulsion is mixed with the negatively charged aggregate, for instance limestone, the emulsion breaks, thereby setting the road-covering formulation. Fatty amines, because of their positive charge, also increase the

adherence of the asphalt to the aggregate. For di- and polyamines, asphalt emulsification is by far the largest application and they are also the most important surfactants for this purpose.

Other Applications. Significant amounts of primary amines are used as fertilizer anticaking agents. Frequently, fatty amine salts are also added to other mineral products to prevent caking of the powdered mineral.

There are many other applications for fatty amines in *agriculture* as emulsifiers, adjuvants, and intermediates in pesticide production. Much of their usefulness relies on the controllable lipid solubility, which aids penetration or absorption of many active pesticides. Among the emulsifiers used are ethoxylated amines and quaternary ammonium compounds. Some of the surfactants also can act as foaming agents or foam stabilizers [223].

Neutralization of various herbicidal acids with fatty amines enhances their activity because the corresponding salts are more soluble in oil and less volatile than the free amines [224–227]. In some cases, the *N*,*N*-dimethylalkylamines were found to control the growth of suckers or unwanted leaves, thereby producing a better grade of product, for example, in tobacco [228]. The reaction of dodecylamine and cyanamide leads to dodecylguanidine (Dodine from ACC, Agrimont, Chemolimpex, and Drexel), which is an excellent fungicide for fruit trees.

Many fatty alkylamine derivatives are used as additives in plastic formulations. For example, bis(2-hydroxyethyl)alkylamines are added to polypropylene or polyethylene as internal *antistatic agents*, either as 100 % amines or as a 75 % solid masterbatch to prevent static charge buildup at low humidities.

Fatty amines, diamines, and ethoxylated amines also can be used as *pigment-grinding aids* and as *dispersants* for pigments in paints, coatings, and magnetic tape. The most widely used compound is *N*-tallow-1,3-propanediammonium dioleate. The amine compound coats the pigment particle, making it more readily and evenly dispersible in the formulation.

The *organo-clay* market also is a very large user of quaternary fatty amines. Most of this market is satisfied with methyl or benzyl quaternary ammonium chlorides produced from mono- or dihydrogenated tallow amine. In either case, the cations of the quaternary ammonium chloride are exchanged with those of the clay, mostly bentonite, to produce clay platelets separated with a hydrophobic compound. These organo-clay products are used as thickening agents, mainly in drilling muds and oil-based coatings, but also in the paint industry.

Some primary amines, amine salts, di- and polyamines, e.g., lauryl and tallow amines, posess biocidal properties; monoalkyl quaternary amines with a $C_{10}-C_{18}$ chain act as germicides and antiseptics and therefore have a wide range of biocidal applications, for example, in households, swimming pools, and oil fields.

Primary amines are also important lubricants since their polar nitrogen end attaches to metals while the nonpolar chains form an oily film above the surface. They are also used as petroleum additives. Secondary amines have few direct uses and are mainly used as intermediates for ethoxylation or quaternization. Tertiary amines with three long chains are of minor commercial significance, but can be used, for instance, as deicers for motor fuels. The fatty alkyldimethylamines are used almost exclusively as intermediates for alkyl betaines, amine oxides, and quaternary ammonium salts.

7.5. Economic Aspects

The economics of fatty amines production generally depend on the worldwide fat and oil market process. Most of the fatty amine products are made from tallow and coconut oils; others are made from oils such as soybean, palm, and cottonseed. Minor amounts of tall oil acids are used. When pure chain lengths are required, these can be obtained by fractionating the acid mixture found in the initial triglyceride. Pure fractions are much more expensive than mixtures. Primary and secondary amines have a much larger market than tertiary amines.

The nitrile route, which is mainly used for the production of primary and secondary amines, accounted for 300 000 t/a world capacity in 1996 for all alkylamines and their derivatives and has decreased since the early 1990s from about 370 000 t/a due to declining demand for the poorly biodegradable dihydrogenated tallow dimethyl ammonium salts for fabric softeners. The

fatty alcohol and α-olefin route, which is mainly used for the production of alkyldimethylamines and their derivatives, is less important but is expected to surpass the nitrile route in the long run. In Europe, the largest producers employing the nitrile route are Akzo Nobel, Clariant, Ceca, and Olefina, in North America Witco and Akzo Nobel, in South America Akzo Nobel, Clariant, and Quimi Kao, in Asia Kao and Lion-Akzo.

The most important producers of *N,N*-dimethyl fatty amines are Procter & Gamble, Albemarle, and Lonza in the United States, Clariant, Albright & Wilson, and Kao in Europe, and Kao and Lion-Akzo in Asia. Worldwide demand was estimated at about 100 000 t/a in 1998. In 1988 it was only ca. 75 000 t/a. North America accounts for 59 % of the installed capacity, Europe for 28 %, and Asia for 8 %.

Because most fatty amines offered commercially contain mixed alkyl chain lengths, trade names are common; a comprehensive list can be found in [229]. In Europe, about 20 000 t were sold in 1996 as the underivatized primary, secondary or tertiary amines.

8. Diamines and Polyamines

8.1. Diamines

8.1.1. 1,2-Diaminoethane (Ethylenediamine)

(For triethylenediamine, see page 23)

Physical Properties. 1,2-diaminoethane [*107-15-3*], EDA, $C_2H_8N_2$, M_r 60.10, is a colorless liquid, *mp* 10.9 °C, *bp* 117 °C (at 101.3 kPa), d_4^{20} 0.8978, n_D^{20} 1.4571.

Viscosity

t, °C	25	60	100
η, mPa · s	1.35	0.7	0.4

Vapor pressure

t, °C	20	40	60	80	100
p, kPa	1.21	3.87	11.13	26.53	55.99

Flash point	39.4 °C	
Ignition temperature (class T2)	390 °C	
Explosion limits in air	2.7 and 16.6 vol % (corresponding to 67.4 and 415 g/m^3)	
Specific heat capacity	3.41 J g^{-1} K^{-1}	(at 100 °C)
	3.45 J g^{-1} K^{-1}	(at 110 °C)
	3.50 J g^{-1} K^{-1}	(at 120 °C)
Heat of vaporization	636.4 J/g (at 0.1 MPa)	
	660 J/g (at 40 kPa)	

Vapor pressures, thermodynamic data, densities, and viscosities have been shown in graphical form [230]. Diaminoethane is infinitely miscible with water, methanol, diethyl ether, acetone, and benzene but is only slightly soluble in lower hydrocarbons. It reacts, however, with carbon tetrachloride or methylene chloride. It forms binary azeotropes with water, several alcohols, or toluene [231].

Chemical Properties. As a primary diamine, diaminoethane forms stable mono- and diacid salts. The free base can be liberated from these salts by inorganic alkali solutions. The mononitrate and dinitrate are highly explosive in the dry state. The reaction of diaminoethane with chloroacetic acid or with formaldehyde and hydrogen cyanide or an alkali-metal cyanide to give ethylenediaminetetraacetic acid or its salts is particularly important (→ Ethylenediaminetetraacetic Acid and Related Chelating Agents). Diaminoethane forms complex salts with salts of copper, manganese, cobalt, and other transition elements.

If diaminoethane is heated with a fatty acid under conditions favoring dehydration, the product is a mono- or diamide, which can be converted into an imidazoline by cyclization. At high temperatures and pressures and in the presence of a catalyst, ammonia is eliminated from diaminoethane, and the resulting product undergoes cyclization to give piperazine. Diaminoethane reacts with aldehydes and ketones to give Schiff bases, which in turn can be hydrogenated to give secondary amines. The Schiff base can also cyclize to afford imidazolidines. Condensation with 1,2-diketones results in the elimination of water to give the corresponding 2,3-dihydropyrazines, which can be readily dehydrogenated to pyrazines [232]. Phosgene reacts with diaminoethane to give the hydrochloride of *N,N′*-ethyleneurea (2-imidazolidone) [233]. One mole of diaminoethane reacts with

two moles of carbon disulfide in the presence of a basic catalyst to give ethylene bisdithiocarbamate [234]. With only one mole of carbon disulfide, ethylenethiourea is formed. Similarly, ethyleneurea is obtained from carbon dioxide. With two moles of acrylonitrile, diaminoethane undergoes a smooth cyanoethylation reaction [235].

Production. 1,2-Diaminoethane is mainly produced by treating ethylene dichloride (EDC) with aqueous or liquid ammonia at about 100 °C in the liquid phase [236]. This so-called EDC process has been modified frequently [237]; the reactant ratio, product recycle, pH, reactor geometry, temperature, and pressure control the product mix. Byproducts include the higher oligomers diethylenetriamine (DETA), triethylenetetramine (TETA), and tetraethylenenpentamine (TEPA). An unavoidable coproduct of the EDC process is the amine hydrochloride, which must be neutralized with caustic soda, lime, or other bases to form, e.g., sodium or calcium chloride. Ethylenediamine is either extracted or distilled from the aqueous stream after neutralization. If deemed necessary, the higher amines can be recycled to optimize EDA production and vice versa. About two-thirds of the installed ethylenediamine capacity still relies on the EDC process.

A second process is the reaction of monoethanolamine with ammonia and hydrogen over a nickel or cobalt catalyst at 20 MPa and 150 – 230 °C [238]. The yield of 1,2-diaminoethane is 74 %, based on an ethanolamine conversion of 93 %. Byproducts are mainly DETA and piperazine, but also aminoethylpiperazine (AEP) and hydroxyethylpiperazine (HEP). The monoethanolamine process has cost advantages over the ethylene dichloride process, circumvents chloride disposal, and prevents the formation of chlorinated hydrocarbons. Lower amines can be recycled to increase the amount of higher ethanolamines; cyclic products are much more abundant than in the EDC process. Product distribution is dependent on reactant ratio, temperature, pressure, and conversion. Nickel – rhenium catalysts have often been employed [239], but many other nickel catalysts with different promoters have also been suggested, for instance, Ni – Re – B supported on alumina [240] or Ni – Co – Cu – Re – B on silica [241].

A third important and very cost effective production process is the reaction of ethylene oxide with ammonia [242], as developed by Berol (now Akzo) in Sweden. Among the byproducts of this process are DETA, piperazine and di- and triethanolamine. Union Carbide has recently brought a similar process into operation. The production of diaminoethane by the reaction of formaldehyde with hydrocyanic acid, ammonia, and hydrogen [243], of chloroacetyl chloride with ammonia [244], and by hydrogenation of aminoacetonitrile [245] are of lesser importance.

Quality, Analysis, and Storage. The purity of diaminoethane, determined by titration and gas chromatography, is usually above 99 %. For storage, containers made of stainless steel and aluminum are preferred to avoid deterioration of the color number when the product is stored for long periods. Because it is corrosive, EDA should not be stored in containers made of copper, copper alloys, or uncoated iron. Frequently containers made of iron coated with plastics, such as Lupolen (BASF) or phenolic resins, are used for shipping and storing diaminoethane. Tin-lined drums can also be employed. Because the amine is hygroscopic and reacts with carbon dioxide in the air, tanks must be flushed with nitrogen before use. This also avoids discoloration during storage.

Uses. Diaminoethane is mainly used in detergents, resins, crop protection agents, paper chemicals, lubricants, and pharmaceuticals. The chelating agent ethylenediaminetetraacetic acid (EDTA) and its salts are important products, in particular in the United States. They are made by reaction of EDA with formaldehyde and hydrogen cyanide or sodium cyanide together with an excess of sodium hydroxide. Tetraacetylethylenediamine (TAED), which is obtained from EDA, is used in the detergent industry as a cold-bleach activator. It has become the fasted-growing EDA product in the last years. Hydroxyethylethylenediamine is also converted into chelating agents. Several nitrogen-containing surfactants are produced from fatty acids and EDA or aminoethylethanolamine, available from EDA and ethylene oxide. Nonreactive polyamide resins produced from EDA and diacids also consume large amounts of EDA. They find use as adhesives and for printing inks.

The zinc and manganese salts of ethylenebisdithiocarbamic acid, obtained from EDA, are used as fungicides (maneb, mancozeb, zineb or metiram) and have a significant market. Other fungicides based on EDA are known, e.g., those of the imidazoline type.

The EDA-derivative *N,N*-ethylene bis(stearamide) (EBS) has lubricating properties and is used as a mold-release agent, for the processing of thermoplastic resins, in paper coating, wire production, etc. EDA is also used for gasoline and lubricant additives and for surfactant production.

Diaminoethane – polyester condensates that are hydroxymethylated with formaldehyde can be used as plasticizers for phenol – formaldehyde resins [246]. The use of condensates of diaminoethane, epoxides, and urea as nitrogen-containing polyol components for the production of polyurethane foams is proposed in [247]. The addition of EDA to viscose fiber spinning baths is said to improve the tensile strength of the fiber [248]. In the wet spinning of polyurethane fibers, diaminoethane is a rapid-action curing agent [249]. The incorporation of diaminoethane into diisocyanate – polyester prepolymers results in useful polymers for the production of elastic polyurethane fibers [250]. Ethyleneurea derivatives prepared from diaminoethane are used for textile finishing. Diaminoethane is employed as a stabilizer for rubber latex. In the mineral oil industry, diaminoethane can act as a stabilizer for halogen-containing high-pressure lubricating oils [251] and, in the form of Schiff bases with ketones, is also used as a metal deactivator [252].

Economic Aspects. Ethylenediamine and its homologues are large-scale chemical products. The global demand for ethyleneamines in 1998 was estimated at 250 000 t [253]; capacities are around 340 000 t/a. The European market is ca. 100 000 t/a with an annual growth rate of 3 – 4 % [254]; the U.S. market has a similar size, and the Japanese is ca. 15 000 t/a. Major producers are Union Carbide, Dow, Akzo Nobel, Tosoh, BASF, and Bayer. In the United States and Japan, the ethylenediamine market is smaller than that of the higher ethyleneamines, and vice versa in Europe.

8.1.2. Diaminopropanes

In the past few years, the demand for diaminopropanes and in particular for *N*-substituted 1,3-diaminopropanes has increased sharply in a large variety of fields.

1,2-Diaminopropane [*78-90-0*], propylene-1,2-diamine, $C_3H_{10}N_2$, M_r 74.13, *mp* – 36.6 °C, *bp* 120.9 °C (at 101.3 kPa), d_4^{20} 0.872, n_D^{20} 1.446, η 1.6 mPa · s (at 20 °C), flash point 33 °C, is a colorless liquid that is very hygroscopic and miscible with water and most organic solvents. It forms azeotropes with butanol, 2-methylpropanol, and toluene and has a strong ammoniacal odor.

Because 1,2-dichloropropane does not react smoothly with ammonia, 1,2-diaminopropane is usually prepared by aminating a mixture of 2-amino-1-propanol and 1-amino-2-propanol, which is obtained from propylene oxide and ammonia [255]. The process differs from corresponding processes for the production of diaminoethane in that the temperature in the catalytic amination is higher (190 – 230 °C). Producers of 1,2-diaminopropane include Bayer and BASF.

1,2-Diaminopropane is used as an intermediate for crop-protection agents, e.g., Basfungin (BASF). Analogous to the ethylenediamine derivatives, the zinc dithiocarbamate propineb (Bayer) acts as a fungicide. Especially in the United States, derivatives of the amine are used as fuel and lubricant additives.

1,3-Diaminopropane [*109-76-2*], propylene-1,3-diamine, trimethylenediamine, propanediamine, $C_3H_{10}N_2$, M_r 74.13, *mp* – 11.8 °C, *bp* 136 °C (at 101.3 kPa), d_4^{20} 0.8834, n_D^{20} 1.459, η 2.0 mPa · s (at 20 °C), flash point 48 °C. 1,3-Diaminopropane is a colorless liquid that is miscible with water and most organic solvents.

1,3-Diaminopropane is produced in a two-stage continuous process, under a pressure of

10 – 20 MPa. In a first reactor, acrylonitrile reacts with excess ammonia at 70 – 100 °C to give 2-aminopropionitrile and bis(cyanoethyl)amine. The mixture of aminonitriles is then hydrogenated in a downstream reactor over a fixed-bed catalyst (cobalt or nickel) at 60 – 120 °C to give 1,3-diaminopropane and bis(aminopropyl)amine [256]. The yield of 1,3-diaminopropane can be increased by adding a polar solvent and water or by using a large excess of ammonia. Most of the 1,3-diaminopropane produced is converted into the textile-finishing agent 1,3-dihydroxymethylhexahydropyrimid-2-one. 1,3-Diaminopropane is also utilized for the production of a chelating agent used in the photo industry and for anticorrosion agents.

***N*-Substituted Diaminopropanes.** *N*-Substituted 1,3-diaminopropanes can be prepared from acrylonitrile and an amine, also with such a two-stage procedure. It is usually more efficient to produce the substituted aminopropionitrile batchwise and then hydrogenate it continuously in the presence of ammonia [257]. In some cases, hydrogenation also can be carried out batchwise over Raney nickel or Raney cobalt. A primary amine or ammonia reacts with acrylonitrile in a molar ratio of about 1/2 to give (after subsequent hydrogenation) alkylbis(aminopropyl)amine, $RN[(CH_2)_3NH_2]_2$, as the principal product, whereas until the molar ratio exceeds 1/1, the principal product is a 1-amino-3-alkylaminopropane, $RNH(CH_2)_3NH_2$. Dialkylamines give 1-amino-3-dialkylaminopropanes.

Major producers of diamines, oligoamines, and polyamines of acrylonitrile include Huntsman and BASF.

The following liquid, water-miscible *N*-substituted diaminopropanes are industrially important. Their chief use is as components of epoxy resins:

1-Amino-3-methylaminopropane [*6291-84-5*], *N*-methyl-1,3-propanediamine, methylaminopropylamine, $C_4H_{12}N_2$, M_r 88.15, *bp* 140 – 141 °C (at 101.3 kPa), d_4^{20} 0.852, n_D^{20} 1.4479, flash point 35 °C, is a byproduct of the production of *N*-methyldipropylenetriamine and results from addition of methylamine to acrylonitrile followed by hydrogenation.

1-Amino-3-dimethylaminopropane [*109-55-7*], 3-dimethylamino-1-propylamine, DMAPA, *N,N*-dimethyl-1,3-diaminopropane, $C_5H_{14}N_2$, M_r 102.18, *mp* < – 60 °C, *bp* 133 °C (at 101.3 kPa), d_4^{20} 0.8112, n_D^{20} 1.4350, η 1.6 mPa · s (at 20 °C), flash point 32 °C, ignition temperature 305 °C (class T2), is a colorless liquid and a lachrymator.

It is produced by addition of dimethylamine to acrylonitrile and subsequent hydrogenation in the presence of ammonia. DMAPA is used primarily for the synthesis of betaines which are employed as personal care products and for dish washing. Of minor importance is the consumption for the production of flocculants and ion exchangers.

1-Amino-3-diethylaminopropane [*104-78-9*], *N,N*-diethyl-1,3-propanediamine, *N,N*-diethyl-1,3-diaminopropane, *N,N*-diethylaminopropylamine, $C_6H_{18}N_2$, M_r 130.2, *mp* – 60 °C, *bp* 169 °C (at 101.3 kPa), d_4^{20} 0.829, n_D^{20} 1.4424, η 1.4 mPa · s (at 20 °C), flash point 53 °C is made by addition of diethylamine to acrylonitrile and subsequent hydrogenation. The market for this product is relatively small.

1-Amino-3-cyclohexylaminopropane [*3312-60-5*], *N*-cyclohexylpropylene-1,3-diamine, *N*-cyclohexyl-1,3-propanediamine, $C_9H_{20}N_2$, M_r 156.27, *mp* – 16 °C, *bp* 113 °C (at 1.3 kPa), d_4^{20} 0.9154, n_D^{20} 1.4810, η 9.4 mPa · s (at 20 °C), flash point 103 °C, ignition temperature 205 °C (class T3) is made by addition of cyclohexylamine to acrylonitrile and subsequent hydrogenation.

N,N,N',N'-Tetramethyl-1,3-propanediamine [*110-95-2*], $C_7H_{18}N_2$, M_r 130.23, *mp* < –70 °C, *bp* 145 – 146 °C (at 1.3 kPa), d_4^{19} 0.7837, n_D^{20} 1.4234, flash point 31 °C can be made by methylation of 1,3-diaminopropane with formaldehyde or from dimethylaminopropionitrile and dimethylamine and is an intermediate for corrosion inhibitors, textile auxiliaries, flotation agents, and emulgators. It is also employed as a catalyst for polyurethanes and as a hardener for epoxy resins.

8.1.3. Higher Diamines

1,3-Diaminobutane [*590-88-5*], $C_4H_{12}N_2$, M_r 88.15, *bp* 138 – 141 °C (at 101.3 kPa), d_4^{20} 0.8536, n_D^{20} 1.4449, can be produced from crotonaldehyde by amination under hydrogenation conditions [258].

Diamines with four to five carbon atoms are important intermediates for pharmaceuticals. However, the production of these diamines is restricted by the fact that the starting materials are difficult to obtain and that there is a strong tendency for cyclization during preparation.

1,4-Diaminobutane [*110-60-1*], tetramethylenediamine, putrescine, $C_4H_{12}N_2$, M_r 88.15, *mp* 27 – 28 °C, *bp* 158 – 159 °C (at 101.3 kPa), d_4^{25} 0.8704, n_D^{20} 1.4569, flash point 63 °C, occurs as colorless crystals that are soluble in water and conventional organic solvents.

1,4-Diaminobutane can be produced from 1,4-dichloro-2-butene or 1,4-dihalobutane (obtainable from the reaction of butadiene or tetrahydrofuran with a halogen), preferably via the phthalimido compounds. Alternatively, 1,4-diaminobutane can be prepared by hydrogenating succinodinitrile [259].

1,5-Diaminopentane [*462-94-2*], pentamethylenediamine, cadaverine, $C_5H_{14}N_2$, M_r 102.18, *mp* 9 °C, *bp* 178 – 180 °C (at 101.3 kPa), d_4^{25} 0.867, n_D^{20} 1.4582, flash point 62 °C, can be prepared by methods similar to those described for 1,4-diaminobutane. The starting materials are 1,5-dichloropentane (obtainable from tetrahydropyran), glutarodinitrile, or glutaraldehyde (e.g., Relugan, BASF). The compound is hygroscopic and has a very bad odor.

1,8-Diaminooctane [*373-44-4*], octamethylenediamine, $C_8H_{20}N_2$, M_r 144.26, *mp* 52 – 53 °C, *bp* 225 – 226 °C (at 101.3 kPa), flash point 165 °C is hygroscopic. It is used for the production of fungicides and is obtained by hydrogenation of suberonitrile (1,6-dicyanohexane).

1,10-Diaminodecane [*646-25-3*], decamethylenediamine, $H_2N(CH_2)_{10}NH_2$, $C_{10}H_{24}N_2$, M_r 172.31, *mp* 61 – 62 °C, *bp* 140 °C (at 1.6 kPa).

1,12-Diaminododecane [*2783-17-7*], $H_2N(CH_2)_{12}NH_2$, $C_{12}H_{28}N_2$, M_r 200.37, *mp* 66 – 67 °C, *bp* 304 °C (at 101.3 kPa), flash point 155 °C can be used as a spacer in affinity chromatography.

Diamines containing more than six carbon atoms can be obtained readily by hydrogenating the corresponding dinitriles over a Raney nickel catalyst in a batch procedure under pressure at up to 125 °C. A five- to tenfold excess of liquid ammonia is used, with or without methanol solvent [260].

Higher diamines can be prepared continuously, as described for the production of hexamethylenediamine. For methods of preparing specific higher diamines, see [3].

2-(Diethylamino)ethylamine [*100-36-7*], *N,N*-diethylethylenediamine, 1-amino-2-(*N,N*-diethylamino)ethane, *N,N*-diethyl-1,2-ethanediamine, diethylaminoethylamine,

$C_6H_{16}N_2$, M_r 116.21, *mp* < −70 °C, *bp* 146 °C (at 101.3 kPa), d_4^{20} 0.8222, n_D^{20} 1.4360, flash point 30 °C.

1-Diethylamino-4-aminopentane [*140-80-7*], *N,N*-diethyl-1,4-pentanediamine, novoldiamine, $C_9H_{22}N_2$, M_r 158.29, *bp* 191 °C (at 101.3 kPa), d_4^{20} 0.821, n_D^{20} 1.4442, flash point 68 °C, is a colorless liquid that is soluble in water and the usual organic solvents.

The diamine is produced by a conventional method, for example, by aminating 1-diethylaminopentan-4-one under hydrogenation conditions, by hydrogenating the oxime, or by aminating 1-diethylaminopentan-4-ol. The ketone is obtained from 2-chloroethyldiethylamine by synthesis of the acetoacetate, and 1-diethylaminopentan-4-ol is obtained by Mannich condensation of diethylamine, formaldehyde, and 1-butyn-3-ol followed by hydrogenation of the product, or is prepared from 1-methyltetrahydrofuran [261], [262]. Producers of 1-diethylamino-4-aminopentane are BASF and some Chinese producers. Derivatives of 1-diethylamino-4-aminopentane are particularly important as antimalarial agents [262] (e.g., chloroquine from Bayer).

3-Aminomethyl-3,5,5-trimethylcyclohexylamine [*2855-13-2*], isophorone diamine, IPDA, (5-amino-1,3,3-trimethyl-1-cyclohexylmethyl)amine, 1-amino-3-aminomethyl-3,5,5-trimethylcyclohexane, $C_{10}H_{22}N_2$, M_r 170.30, *mp* 10 °C, *bp* 247 °C (at 101.3 kPa), d_4^{20} 0.922, n_D^{20} 1.4880, flash point 112 °C.

This specialty diamine is produced by Degussa-Hüls and BASF. It is made from isophorone nitrile, ammonia, and hydrogen, which leads to simultaneous imination and hydrogenation of the resulting imine and nitrile groups [263]. Catalysts employed are mainly cobalt or ruthenium. Isophorone diamine is employed as a hardener for epoxy resins and as an intermediate for isophorone diisocyanate; its market is considerable. Very important for the applications is the *cis*/*trans* isomer ratio, which should be as high as possible, since the trans isomer reacts more sluggishly.

***N,N,N′,N′*-Tetramethyl-1,6-hexanediamine** [*111-18-2*], *N,N,N′,N′*-tetramethylhexamethylenediamine, $C_{10}H_{24}N_2$, M_r 172.31, *bp* 209–210 °C (at 101.3 kPa), d_4^{20} 0.7981, n_D^{20} 1.4363, flash point 73 °C, can be made from adipodinitrile and dimethylamine or from 1,6-hexanediamine and formaldehyde and is used for instance as a catalyst for polyurethanes and hardener for epoxy resins.

8.2. Oligoamines and Polyamines

8.2.1. Physical Properties

Diethylenetriamine [*111-40-0*], DETA, bis(2-aminoethyl)amine, 2,2′-diaminodiethylamine, 3-azapentane-1,5-diamine, $C_4H_{13}N_3$, M_r 103.17, is a colorless liquid, *mp* −39 °C, *bp* 207 °C (at 101.3 kPa), d_4^{20} 0.9542, n_D^{20} 1.4859, η 7 mPa · s (at 20 °C).

Vapor pressure

t, °C	20	89	174
p, kPa	0.049	1.333	40.0

Flash point	102 °C
Ignition temperature	330 °C (class T2)
Specific heat capacity	3.44 J g^{-1} K^{-1} (at 190 °C) 3.48 J g^{-1} K^{-1} (at 200 °C) 3.53 J g^{-1} K^{-1} (at 210 °C)
Heat of vaporization	456.4 J/g (at 0.1 MPa) 485.7 J/g (at 40 kPa)
Dissociation constant	7.07×10^{-5}
Surface tension	43.8 mN/m (at 25 °C) 40.8 mN/m (at 50 °C)
Coefficient of expansion	9.1×10^{-4} (at 55 °C).

The amine is infinitely miscible with water, methanol, acetone, ether, and benzene, but insoluble in heptane. Because of its reactivity, CCl_4 cannot be used as solvent. DETA is hygroscopic and has a strong ammoniacal odor.

Triethylenetetramine [*112-24-3*], TETA, *N,N′*-bis(2-aminoethyl)ethylenediamine, 1,8-diamino-3,6-diazaoctane, 1,4,7,10-tetraazadecane, $C_6H_{18}N_4$, M_r 146.24, is a colorless to yellowish oily viscous liquid, *mp* − 35 °C, *bp* 277 °C (at 101.3 kPa), d_4^{20} 0.9818, n_D^{20} 1.4986, η 26.7 mPa · s (at 20 °C).

Vapor pressure

t, °C	20	144	240
p, kPa	0.001	1.33	40.0

Flash point	135 °C
Heat of vaporization	374.7 J/g (at 0.1 MPa) 397.8 J/g (at 40 kPa)
Dissocation constant	6.7×10^{-5}

TETA is hygroscopic, corrosive, and has a strong ammoniacal odor. With water a crystalline hydrate is formed. Like DETA, it is completely miscible with water and many polar organic solvents, but less so with lipids; with CCl_4 a violent reaction occurs. Its four pK_a values are 3.32, 6.67, 9.20, and 9.92. Technical-grade TETA is sometimes available as a distillation cut that also contains branched isomers and cyclic compounds.

Tetraethylenepentamine [*112-57-2*], TEPA, 1,4,7,10,13-pentaazatridecane, $C_8H_{23}N_5$, M_r 189.30, is a slightly yellowish viscous liquid, *mp* − 40 °C, *bp* 340 °C (at 101.3 kPa), d_4^{20} 0.9994, n_D^{20} 1.505, η 96.2 mPa · s (at 20 °C). Technical-grade TEPA may be available as a distillation cut that also contains branched isomers and cyclic compounds.

Vapor pressure

t °C	20	195	300
p, kPa	0.0013	13.5	40

Dissociation constant	6.5×10^{-5}
Flash point	163 °C

Tetraethylenepentamine is infinitely miscible with water, methanol, acetone, benzene, and diethyl ether but is insoluble in heptane and reacts violently with CCl_4.

Pentaethylenehexamine [*4067-16-7*], PEHA, $C_{10}H_{28}N_6$, M_r 232.37, *mp* − 26 °C, *bp* 136 – 144 °C (at 0.02 kPa), d_4^{20} 1.0020, flash point 186 °C, commercially is of minor importance. Technical-grade PEHA may be available as a distillation cut that also contains branched isomers and cyclic compounds.

Dipropylenetriamine [*56-18-8*], 1-amino-3-(3-aminopropyl)aminopropane, bis(aminopropyl)amine, $C_6H_{17}N_3$, M_r 131.22, *mp* − 15.1 °C, *bp* 238 °C (at 101.3 kPa), d_4^{20} 0.9386, n_D^{20} 1.4846, flash point 118 °C, vapor pressure < 0.001 kPa at 20 °C, dissociation constant 3.96×10^{-4}, η 9.6 mPa · s (at 20 °C), is miscible with water, methanol, and conventional organic solvents.

***N*-Methyldipropylenetriamine** [*105-83-9*], 1-amino-3-*N*-methyl-*N*-(3-aminopropyl)-aminopropane, $C_7H_{19}N_3$, M_r 145.25, *mp* − 32 °C, *bp* 234 °C (at 101.3 kPa), d_4^{20} 0.9040, n_D^{20} 1.4732, η 7.4 mPa · s (at 20 °C), flash point 107 °C, ignition temperature 250 °C (class T3),

is miscible with water and conventional organic solvents.

3-(2-Aminoethyl)-aminopropylamine [*13531-52-7*], *N*-(2-aminoethyl)-1,3-diaminopropane, $C_5H_{15}N_3$, M_r 117.19, *mp* −10 °C, *bp* 80 °C (at 0.3 kPa), d_{20}^{20} 0.9401, n_D^{20} 1.4805, flash point 98 °C.

***N,N′*-Bis(3-aminopropyl)-1,2-diaminoethane** [*79554-59-9*], *N,N′*-bis(3-aminopropyl)ethylenediamine, $C_8H_{22}N_4$, M_r 174.3, *mp* −1.5 °C, *bp* 170 °C (at 0.3 kPa).

$H_2N(CH_2)_3NHCH_2CH_2NH(CH_2)_3NH_2$

8.2.2. Chemical Properties

Because they possess terminal primary amino groups, condensates of 1,2-diaminoethane react very much like 1,2-diaminoethane itself. The higher condensates of 1,3-diaminopropane have similar properties. Dibasic acids react with oligoamines and polyamines to give polyamides [264]. A number of urea compounds can be obtained from oligoamines, e.g., diethylenetriamine, or from polyamines [265]. These amines react with aliphatic dihalides to give water-soluble cationic products [266] and with epichlorohydrin to give anionic polymers [267].

In a manner similar to diaminoethane, diethylenetriamine reacts with formaldehyde and sodium cyanide to give diethylenetriaminepentaacetic acid, which also has complex-forming properties. Diethylenetriamine undergoes also a smooth cyanoethylation reaction [235]. The oligoamines react directly with formaldehyde to give permethylated products. At elevated temperatures, diethylenetriamine can be cyclized to piperazine; if the temperature is about 400 °C, the cyclization reaction gives pyrazine directly [268].

8.2.3. Production, Analysis, and Uses

Diethylenetriamine is obtained as a byproduct in the synthesis of 1,2-diaminoethane from dichloroethane (ethylene dichloride, EDC), ethylene oxide, or ethanolamine and ammonia. Triethylenetetramine, tetraethylenepentamine, and pentaethylenehexamine are other byproducts from the EDC process for 1,2-diaminoethane. More selective production methods have been described as well, in particular for DETA, mostly starting with EDA [269].

A number of polyamines are obtained by cyanoethylation of diaminoethane or a diaminopropane with acrylonitrile, followed by hydrogenation of the product [133]. For instance, dipropylenetriamine is produced as byproduct by hydrogenation of the addition product of ammonia and acrylonitrile [256]; it is used as curing agent for epoxy resins. *N*-Methyldipropylenetriamine is obtained from methylamine and acrylonitrile.

The regulations governing storage and transportation of the oligoamines and polyamines are the same as those for 1,2-diaminoethane. For storage of DETA, TETA, and TEPA, plastic-lined, stainless steel or aluminum containers are best suited. Carbon steel leads to iron contamination. A nitrogen atmosphere without carbon dioxide is necessary for DETA. TETA and TEPA are sometimes stored under air, but nitrogen is superior. Purity is determined preferably by titration, and analysis is performed by fractional distillation. The oligoamines, e.g., diethylenetriamine, can be also analyzed by gas chromatography, but this method is unsuccessful for the higher polyamines, owing to their low vapor pressures.

Many uses of the higher acyclic ethyleneamines are similar to those of EDA itself, the most important being lubricant oil additives, polyamide resins, epoxy curing agents, surfactants, and oil field chemicals [231]. Polyisobutenylsuccinimides derived from TETA, TEPA, or PEHA are important motor oil additives. Polyamide resins produced from DETA or TETA with adipic acid are treated with epichlorohydrin and used as wet-strength additives in paper manufacture. Polyamine-modified urea – formaldehyde resins are also used as wet-strength additives for cellulose fibers. DETA and

TETA or their ethoxylation products are used as curing agents for epoxy resins. Polyamine amides possessing terminal primary amino groups, which are prepared from fatty acids and polyamines, serve the same purpose.

Amidoamines obtained from the reaction of a fatty acid and a polyamine, in particular DMAPA and DETA, have similar uses to the more expensive fatty amines, e.g., as asphalt emulsifiers, flotation agents, and corrosion inhibitors. If the solid amidoamines are further heated to 200 – 240 °C, cyclization to imidazoline derivatives is induced. Since these are liquids they posses handling advantages over the amidoamines; the uses are similar, and the polyamines mostly used for production are DETA and TETA. Polyamine derivatives are also used for textile finishing. The most important DETA applications are chelating agents (diethylenetrinitrilopentaacetic acid) and wet-strength paper additives. The latter application is increasing since the paper industry is replacing melamine – formaldehyde resins with polyamide – epichlorohydrin resins which operate under neutral pH conditions.

9. Chiral Amines

With the trend in modern pharmaceutical and agricultural chemistry towards enantiomerically pure compounds, amines, being important intermediates in both areas, came into demand in their chiral forms. Some can be taken from the chiral pool and others made from it, but a growing proportion of the market for these specialities is being synthesized. Although enantiomeric syntheses or resolutions are sometimes available [270], they tend to use very expensive reagents, so that enzyme-catalyzed processes offer a significant economic advantage. Enzymatic resolution of a racemic mixture affords a pure enantiomer, albeit with loss of the other enantiomer. Both enantiomers are obtained in pure form by enantioselective acylation, after which the (*R*)-amide and the unchanged (*S*)-amine are separated by simple distillation [271], [272]. Formation of diastereomeric salts by neutralizing a racemic amine with an optically active acid and subsequent fractional crystallization can also be used for optical resolution [273].

The chiral amines can be directly incorporated in pharmaceuticals or used as chiral auxilaries in synthesis. For instance, (*S*)-1-phenylethylamine has been used for the optical resolution of the analgesic Naproxen [274].

10. Toxicology and Occupational Health

10.1. General Aspects

The aliphatic amines are highly irritating or corrosive. In their nonprotonated form they are lipid soluble and therefore penetrate rapidly into the lower layers of the exposed tissue. Even in low concentration the vapors cause swelling and damage in the mucous membranes of the eye and the respiratory tract.

Acute Toxicity and Local Effects. Generally, the LD_{50} (rat, oral or dermal) is on the order of 100 – 1.000 mg/kg [275]. The symptoms are caused mainly by high penetrability, corrosion, alkalosis, and, in some cases, by functional interference with nerve-impulse conduction. The LD_{50} values of the hydrochlorides are usually higher because they do not cause corrosion and alkalosis: 1600 – 3200 mg/kg (rat, oral) [275]. Acute toxic values, local effects on exposed skin and eyes, and occupational exposure limits in Germany [276] and the United States [277] are compiled in Table 7.

Irritation and corrosion of the skin and mucous membranes were observed frequently in humans [275], [316], also on exposure to the vapor [317]. Accidental inhalation of large amounts can cause headache, nausea, excitation, and short convulsions [275]. Some aliphatic amines, especially di- and polyamines, can cause sensitization of the skin and the respiratory tract (allergies) [275], [318].

β-Chloroalkylamines have an alkylating potential in addition to their corrosiveness. Therefore, they are suspected carcinogens.

Systemic Toxicity. In neutral media the amines are almost completely protonated to the ammonium compounds. Therefore, interaction with the cation channels of the nerve-cell membranes is possible. This may result in a change of permeability for physiologically important

Table 7. Survey of acute toxicological data and occupational exposure limits of aliphatic amines

Substance	CAS no.	Acute toxicological data						Occup. exposure limits [d] [276], [277]	
		LD_{50} [a] mg/kg	Source	LC_{50} (inhal.) [b] g/m^3	Source	Local irritation [c]	Source	MAK (1998), mL/m^3	TLV (1997), mL/m^3
Ethylamine	[*75-04-7*]	400 – 800 (o, rt)	[278], [279], [280]	12.6 (4 h, 20 – 22 °C, rt)	[281]	c	[282]	10	10
Diethylamine	[*109-89-7*]	450 – 650 (o, rt, ms) 580 – 820 (d, rbt)	[282], [283] [287], [288]	12.1 (4 h, 20 – 22 °C, rt)	[283], [284]	c	[283], [285], [286]	5	5
Triethylamine	[*204-44-8*]	460 – 590 (o, rt, ms)	[283], [288], [289], [282], [290]	10.9 (4 h)	[291]	c	[292], [293]	1	1

Morpholine	[*110-91-8*]	1050 – 1600 (o, rt) ca. 500 – 900 (o, ms)	[313], [314] [315]	-	-	c	[313], [314] [315]	20	20

[a] rt = rat, ms = mouse, rbt = rabbit, o = oral, d = dermal. [b] satur. = saturated atmosphere, rt = room temperature. [c] c = corrosive. [d] n.e. = not established

cations and thus in inhibition of impulse conduction along the nerve fibers. The essential structural element of most local anesthetics is a tertiary amino group. If significant amounts of these substances are present in the blood, effects adverse to the impulse conduction of the heart and especially to the inhibitory neurons of the CNS result. The clinical symptoms range from excitation to clonic convulsions. Consequently, excitation of the CNS with increased blood pressure and short spasms were observed along with irritation and injury to the respiratory tract on accidental inhalation of large amounts of aliphatic amines.

Long-chain mono- and dialkylamines are potential histamine liberators and may produce reddening and edema of the skin and mucous membranes, itching, decreased blood pressure, tachycardia, and bronchioconstriction [275], [319]; the maximum effect occurs with C_{10} monoamines and C_{14} diamines. Certain aliphatic di- and polyamines, such as putrescine [*110-60-1*] ($H_2N(CH_2)_4NH_2$), spermidine [*124-20-9*] ($H_2N(CH_2)_4NH(CH_2)_3NH_2$), and spermine [*71-44-3*] ($H_2N(CH_2)_3NH(CH_2)_4NH(CH_2)_3$-$NH_2$), are found characteristically in proliferating cells and are formed under the influence of hormones, natural growth stimuli, specific tumor promoters, and other factors. Their physiological action is apparently involved in cell division and tissue proliferation [320].

Metabolism. In many cases, little is known about the metabolism of alkylamines. Generally, once absorbed, alkylamines do not accumulate and are rapidly released from the organism, mostly into the urine, either unchanged (e.g., diethylamine, cyclohexylamine) or metabolically converted. Reactions catalyzed by the cytochrome P450 system include the oxidative deamination of primary alkylamines and *N*-dealkylation of secondary and tertiary amines [321]. This enzyme system competes with an unspecific flavin-containing monooxygenase that produces *N*-oxides from tertiary amines and hydroxylamines from secondary amines. Furthermore, *N*-methyltransferases may alkylate mono-, di-, and trialkylamines [321]. In addition, by monoamine oxidase, primary, secondary, and tertiary amines can be oxidatively dealkylated stepwise to aldehydes (or carboxylic acids), ammonia, and hydrogen peroxide [321]. The oxidation rate increases with increasing chain length; methylamine is not transformed by monoamine oxidase [322], [323]. Short-chain mono- and diamines are also oxidized by diamine oxidase (histaminase); those most readily oxidized are 1,4-butanediamine and the $C_5 - C_6$ monoamines.

Secondary amines (including those with cyclic structures), and to some extent tertiary amines, can be chemically transformed into carcinogenic *N*-nitrosodialkylamines in the presence of nitrites or nitrates under reducing conditions.

10.2. Toxicology of Specific Amines

10.2.1. Alkylamines, Cyclic Amines, and Polyamines

Ethylamine [*75-04-7*], alkaline liquid, in neat form gaseous at room temperature, is readily absorbed through the skin and respiratory tract [282], but easily excreted in the urine after partial metabolism [324]. Exposure to the vapor may transiently impair vision in humans ("blue haze") [325]. The odor threshold in air is ca. $0.027 - 0.27$ mL/m^3 (≤ 0.5 mg/m^3) [326], [327]. In rabbits, inhalation of 50 mL/m^3 (94 mg/m^3) for 6 weeks resulted in local and systemic organ lesions (corneal erosions and edemas, pneumonia, peribronchitis, focal muscular degeneration of the heart) [285]. Transient physiological effects were seen after prolonged exposure of rats to vapors ($0.06 - 3.69$ mg/m^3, 90 d) with no effects at 0.015 mg/m^3. At the highest concentration, morphological changes in the lung and cerebral neurons apparently were reversible [326].

Diethylamine [*109-89-7*], alkaline liquid, once absorbed, is rapidly excreted unchanged in the urine [328]. Exposure to low vapor concentrations are reported to transiently impair vision in humans (reduction of sensitivity to light): no-effect threshold $0.022 - 0.028$ mL/m^3 (≤ 0.08 mg/m^3) [326], [329]. The odor threshold in air is ca. $0.02 - 0.3$ mL/m^3 (≤ 0.9 mg/m^3) [329], [330]. Transient physiological effects in rats after 90-d exposure to vapors were reported to already be visible at $0.37 - 4.19$ mg/m^3

with no effects at 0.05 mg/m^3, but with morphological, apparently reversible changes in the lung and cerebral neurons at the highest concentration [326]. On the other hand, 50 mL/m^3 (150 mg/m^3) was the lowest concentration to show mild, but significant effects in the lung and liver of rabbits on prolonged inhalation [285]. There were no visible signs of toxicity following exposure of rats to 25 mL/m^3 (75 mg/m^3) for 120 d, but a moderate, bronchiolar hyperplasia of lymphoid cells [286]. It was assumed that diethylamine may exert a certain neurotoxic effect, which, however, was not confirmed by others [286].

Under experimental conditions, no sensitizing potential was observed [331]. Diethylamine itself showed no mutagenic potential. Although the carcinogenic *N*-nitrosodiethylamine is formed in the presence of nitrite, combined administration in the feed and drinking water gave no evidence of increased tumor incidence in a lifelong study with rats [332].

Triethylamine *204-44-8*, oily, alkaline liquid, once absorbed, is rapidly excreted unchanged or as its *N*-oxide in the urine [333], [334]. Exposure to the vapor may transiently impair vision in humans ("blue haze"): concentrations without visual effect are in the range of 1.4 – 2.7 mL/m^3 [293], [335]. Its exciting effect on the CNS is more pronounced than that exerted by the other lower ethyl homologues; effects on parasympathetically controlled musculature and inhibition of nerve pulse transmission in sypmpathetic ganglia can be explained by inhibition of cerebral monoamine oxidase [292], [335]; however, triethylamine does not inhibit neuromuscular impulse transmission [292]. Under experimental conditions and in humans, no sensitizing potential was observed [335]. The odor threshold in air is reported from < 0.09 to 1.4 mL/m^3 (≥ 0.33 mg/m^3) [326], [335].

Dipropylamine [*142-84-7*], alkaline liquid, may cause headache, nausea, faintness, and lung edema on inhalation. The odor threshold in air is 0.02 – 0.1 mL/m^3 (≤ 0.4 mg/m^3) [295].

Isopropylamine [*75-31-0*], alkaline liquid: Signs of respiratory irritation may occur at about 24 mg/m^3 and above (≥ 10 mL/m^3) in humans [297]. In rats, a NOAEL was defined as 100 mg/m^3 for prolonged inhalation (1 month) [336]. The substance was void of any teratogenic effects after exposure of pregnant rats to up to 1000 mg/m^3 [337]. An odor threshold in air is reported to be between 5 – 10 mL/m^3 (≤ 24 mg/m^3) [297].

Cyclohexylamine [*108-91-8*], alkaline liquid, is readily absorbed by the oral and respiratory route, but only slowly through the skin, and is rapidly excreted in the urine almost unchanged [338]. It has a strong fishlike odor (odor threshold ca. 2.5 mL/m^3 = 10.4 mg/m^3) [299], [338]. First signs of a sympathomimetic effect in humans (elevation of the arterial blood pressure) are reported at a daily dose of 5 mg/kg [338].

Cyclohexylamine has been studied intensively because it is a metabolite of the sweetener saccharin. Intake of either up to 300 mg/kg of the HCl salt daily in the feed of rats for two years and lifelong [339–341] or of up to about 750 mg/kg daily in the feed of mice (0.3 and 0.5 % HCl salt) for ≥ 80 weeks [342], [343] did not lead to higher incidence of tumors. Accelerated basal metabolic rate and reduced spermatogenesis were observed in rats after 90 d [344] at daily doses of 2000 and 6000 ppm (HCl salt), but no such symptoms were evident at 600 ppm (ca. 20 mg amine per kilogram) daily intake. In other long-term feeding studies, no convincing evidence of toxicity was apparent at doses of 5 to ca. 20 mg kg^{-1} d^{-1} [299].

In a multigeneration study (two years, 150 mg/kg daily of cyclohexylammonium chloride), the fertility of rats was not affected adversely in spite of slight atrophy of the testicles [341]. Based on these and other results [345], [346], it is concluded that no mutagenicity, carcinogenicity, or teratogenicity is suspected for cyclohexylamine [347], [338].

4,4′-Diaminodicyclohexylmethane [*1761-71-3*], alkaline solid, was shown to have skin-sensitizing potential [302], [348]. On resorption, predominant clinical signs of intoxication were hyperexcitability, excessive salivation, and convulsions in animals; repeated oral dosing (50 – 100 mg kg^{-1} d^{-1} in rats and mice for 10 and 16 d, respectively, 50 mg/kg in dogs for up to 82 weeks) resulted in gastrointestinal hemorrhagic inflammations, nephritis, and fatty changes to the liver [281], [300], [348]. No

changes in methemoglobin or in other hematological parameters were induced in cats on repeated doses of 50 and 100 mg kg^{-1} d^{-1}, given twice per week over 2 months [281], [301]. Several in vitro [281], [349] and in vivo mutagenicity studies [281], [301] gave no evidence of a mutagenic or clastogenic potential.

Piperazine [*110-85-0*], alkaline solid, is almost completely absorbed from the intestinal tract on oral ingestion. Acute intoxications occasionally follow therapeutic treatment of animals with piperazine salts (as anthelmintics), and symptoms include adverse neurologic events such as ataxia, muscle tremor, muscular weakness, and vomiting [350]. In humans, headache, nausea, coordination disorders, and exanthems have been observed occasionally during repeated intake of piperazine salts in daily doses of 30 – 75 mg/kg [351]. Apparently, sensitizations of the skin and also the respiratory tract can occur; these are also caused by the dihydrochloride [352–354]. Based on several observations, especially in workers in Germany, piperazine was included in the list of allergens which are also suspected of inducing respiratory sensitization, but no MAK value was established [355], [356].

Although experimental data suggest that piperazine itself is unlikely to be mutagenic and carcinogenic, there is strong evidence that the combination with nitrite produces malignant tumors in animals: for reviews, see [357], [358].

1-(2-Aminoethyl)piperazine [*140-31-8*], alkaline liquid: Sensitization was observed in animal experiments [359].

Pyrrolidine [*123-75-1*], alkaline liquid: As with other amines, sympathomimetic action is observed and results in increased blood pressure and a tendency to convulsions [304]. In an inhalation study on male rats [360], exposure to 2.6 mg/m^3 for 6 months caused increasing excitation of the nervous system, inhibition of diuresis and spermatogenesis without impairment of spermatozoon mobility and fertility; however, morphological alterations were evident from an increase in the number of tubuli seminiferi with desquamation of the seminiferous epithelium. Experimental data suggest that pyrrolidine itself is unlikely to be mutagenic [303] and carcinogenic: in limited long-term studies in rats and mice in the presence of nitrite in drinking water to favor nitrosation, there was no evidence of a carcinogenic effect [361], [362].

Ethylenediamine [*107-15-3*], alkaline liquid: Dermatitis related to primary irritation and also to sensitization occurs frequently [275]. Sensitization of the mucous membranes of the respiratory tract with asthmatic symptoms has also been described [363], [364]. After oral administration in rats and mice at up to 1000 mg kg^{-1} d^{-1} of the dihydrochloride salt, no teratogenic effects were produced [365–367], and there was no evidence for an impairment of reproduction in a two-generation study [365]: 250 mg kg^{-1} d^{-1} dihydrochloride salt (ca. 112 mg kg^{-1} d^{-1} base) can be considered the NOAEL [368]. Several in vitro tests gave no evidence for a mutagenic potential [369–371].

3-Dimethylamino-1-propylamine [*109-55-7*], alkaline liquid: There are indications of contact and possibly respiratory allergy in relation to occupational exposure [307]. Less than 0.9 ppm of 3-dimethylaminopropylamine in the workplace air may adversely affect respiratory function [372]. The skin-sensitizing potential was verified in an animal study. In an oral 28-d study with rats (gavage, 7 times per week.), clinical symptoms including pulmonary and cardiac failure were noted at 250 mg kg^{-1} d^{-1}, but no treatment-related effects at a level of 50 mg kg^{-1} d^{-1} [307].

Diethylenetriamine [*111-40-0*], alkaline liquid: sensitization of the skin and possibly respiratory tract occurs frequently [275], [309]. Experience from occupational medicine suggests that the latter has to be considered the main adverse effect that may occur in humans [309]. Following oral administration, diethylenetriamine is readily absorbed and rapidly excreted, mainly via the urine and feces [309]. In rats, no histopathological changes were observed after 90-d feeding up to the highest dietary level of 15 g/kg (ca. 1200 mg kg^{-1} d^{-1}), [373] while in cats and rabbits, repeated oral doses of ca. 200 mg kg^{-1} d^{-1} and above as base or HCl salt resulted in severe gastritis, lung edema or pneumonia, and kidney lesions [281], [309].

Triethylenetetramine [*112-24-3*], alkaline liquid: may induce lung edema on inhalation of its vapors. The compound is also an effective skin sensitizer [275]. Following repeated dosing (ca. 50 mg each, 17 – 55 times) onto the skin of pregnant and nonpregnant guinea pigs, significant amounts were absorbed by the strongly irritated skin, leading to toxic effects in the kidneys, liver, brain, and placenta and causing abortion [310], [374], [375]. Triethylenetetramine proved to be a mutagen in vitro [376] but not in vivo [310].

Hexamethyleneimine, hexahydro-1*H*-azepine [*111-49-9*], for acute toxicity data: see Table 7.

Hexamethylenetetramine [*100-97-0*], HMTA, urotropin, is rapidly absorbed from the gastrointestinal tract, and the majority is excreted unchanged in the urine [311].

Irritation and Sensitization. In animals, HMTA exhibited a skin-sensitizing potential [377]. Several reports in industry [378–380] suggest an association between HMTA exposure and the increased occurrence of irritative, allergic events among workers: this was often encountered with hot processing in the rubber and foundry industries. Sensitized persons frequently showed positive responses on patch testing, although the causative agent remained obscure [379], [381]. They can suffer from asthmatic or asthmalike attacks on inhaling HMTA [382].

Systemic Toxicity. Experience from therapeutic use in the past, especially for the prevention of recurrent urinary tract infections in human patients, support the low toxicity on prolonged oral ingestion of up to 4 g/d per individual. Some 1 – 7 % of the patients experienced untoward events such as gastrointestinal intolerance (nausea, vomiting, abdominal cramps) and unspecific skin reactions (pruritus, urticaria, erythematous eruptions) [383]. Chronic animal studies with HMTA administered in the diet or drinking water did not reveal any evidence of a carcinogenic potential and account for a high chronic NOAEL of more than 1000 mg kg^{-1} d^{-1} [384–386].

Mutagenicity. The majority of studies failed to reveal any in vitro or in vivo genotoxic activity. At cytotoxic or sublethal doses ($\leq$ 10 g/kg) [311], a weak mutagenic effect was found in male mice [387], but there was no positive response at up to 1500 mg/kg [388], while a cytogenetic assay after single oral and repeated doses of one-third of the LD_{50} in mice was clearly negative [389]. Furthermore, the compound is described as mutagenic for larvae of *Drosophila* (dose not specified) [382].

Teratogenicity and Reproduction. In several multigeneration studies on rats, no treatment-related abnormalities or developmental defects in the offspring or reproductive defects in the parental generation were seen following high oral doses of up to more than 1500 mg kg^{-1} d^{-1} [311], [386]. In a study with female beagles (600 and 1250 ppm of HMTA in the feed (15 – 31 mg kg^{-1} d^{-1}), from the 4th to 56th day after mating), slight embryotoxic effects were found at higher doses but no malformations [390].

Morpholine [*110-91-8*], alkaline liquid, is well absorbed by the oral, dermal, and inhalation route, but rapidly excreted, mainly unchanged, in the urine. Experimental evidence suggests that morpholine is unlikely to induce skin sensitization [314], [391].

Common signs of toxicity following repeated dosing are local irritation and inflammations of the stomach, respiratory tract, and eyes, as well as systemic effects primarily on the liver and kidneys. In rats, exposure to 250 mL/m^3 (890 mg kg^{-1} d^{-1}, 6 h/d, 5 d/week, 90 d) [392] and to up to 150 mL/m^3 (543 mg/m^3, 6 h/d, 5 d/week, 104 weeks) [393], [313] produced focal erosions and squamous-cell metaplasia of the nasal cavities and turbinates and ocular irritation, but no hematological or organ effects; at 90 mg/m^3 (25 mL/m^3, subchronic) and 36 mg/m^3 (10 mL/m^3, chronic), no treatment-related effects at all were identified. These data may be taken as NOAELs, although one earlier Russian publication [394] claimed that some adverse effects were conspicuous on the spleen and in the red and white blood counts in rats and guinea pigs after four-month inhalation of 70 mg/m^3 and less (see also [313]).

After oral application, no toxic signs were found in mice receiving 70 – 140 mg kg^{-1} d^{-1} base in drinking water as morpholine oleate for 90 days [396].

In a subacute feeding test (four weeks, rats), a daily dose of 323 mg/kg led to increased weight of the suprarenal gland accompanied by retarded development of body weight; daily doses of 27 and 93 mg/kg were without effect [303], [313].

In isolated cases, morpholine showed a weak mutagenic acticity; however, most of the experimental in vitro and in vivo data confirmed that purified morpholine did not give any evidence of a mutagenic potential [281], [313], [314], [395]. Furthermore, longterm studies (in rats and hamsters with feed containing 0.1 % base [396], in mice with drinking water containing up to 0.24 % base [397], and inhalation of up to 530 mg/m^3 in rats [398]) failed to reveal an inherent cancerogenic potential of morpholine [313], [314]. However, there is a possibility of nitrosation in the presence of traces of nitrous acid or nitrogen oxides [303], [399]: *N*-nitrosomorpholine is a potent carcinogen [313], [395].

10.2.2. Fatty Amines

Skin and Eye Irritation. Fatty amines are local irritants of eyes, skin, and mucous membranes. Both the primary amines and the propanediamines are generally regarded as severely irritating and possibly corrosive. Even dilute solutions (5 %) of fatty amines may cause irreversible damage to the eye; cornea inflammation caused by 1 % solutions heals without permanent effects. Concentrated solutions of salts of fatty amines and quaternary ammonium compounds are almost neutral but they have an irritating potential similar to the free bases. Ethoxylation of fatty amines reduces the irritating effects.

A small number of workers became sensitized to selected fatty amines. Symptoms included skin rash, dermatitis, eye swelling, and a sensation of the skin, described as "crawling". Appropriate skin and eye protection must be worn when handling fatty amines.

Inhalation. At ambient temperatures only the short-chain amines, especially if branched, have sufficient vapor pressure to present any hazard by inhalation. The LC_{100} of 2-ethylhexylamine is 1.3 mg/L (rat, 4 h) [400], whereas exposure to air saturated with *N,N*-di(tridecyl)tridecanamine for eight hours resulted in no deaths [401].

Acute and Chronic Oral Toxicity. None of the fatty amines are highly toxic by ingestion. The more corrosive ones, such as coco-1,3-diaminopropane, have oral LD_{50} values as low as 147 mg/kg, whereas compounds of higher molecular weight, such as di(hydrogenated-tallow) dimethylammonium chloride, are relatively nontoxic, with oral LD_{50} values of 7000 mg/kg and higher [402].

Chronic feeding studies have shown that rats fed with 500 ppm of 1-octadecylamine in the diet for two years showed no observable adverse health effects, whereas dogs fed the same level for twelve months showed mainly nonpathologic irritant effects on the mucosa of the gastrointestinal tract [403].

1. Introduction

Definitions. *Aromatic amines* are organic nitrogen compounds that may be considered derivatives of ammonia (NH_3) with at least one of the hydrogen atoms replaced by an aryl group. The nitrogen must be bound directly to the aromatic ring and so be able to interact with the aromatic π-electron system. The amine can be primary, secondary, or tertiary depending on whether one, two, or three of the protons are replaced by alkyl or aryl groups. The simplest aromatic amine is derived from benzene and is called aniline or benzenamine ($C_6H_5NH_2$). The amines from toluene are referred to as toluidines and from naphthalene as naphthylamines. Pyridine, pyrrole, and others in which nitrogen forms part of the ring are treated not as aromatic amines but as heterocyclic compounds.

Nomenclature. Aromatic amines most often are named by adding the suffix "amine" to the name of the radical (or radicals) replacing one or more of the hydrogen atoms in ammonia, except when some trivial name exists. According to IUPAC nomenclature, the amino (NH_2) or modified amino group (NHR, NRR′) is considered a substituting group of the aromatic hydrocarbon. Therefore, these compounds are named as derivatives of benzene, toluene, naphthalene, and others, e.g., *N,N*-dimethylaminobenzene, $C_6H_5N(CH_3)_2$.

Aniline is generally used as the parent structure for its derivatives unless a carbon atom is attached to the benzene ring or unless a function of higher seniority than amino is present in the molecule. Important derivatives of aniline are named as such, e.g., *N*-methylaniline, *p*-nitroaniline, chloroaniline, whereas the sulfonic acids are named as derivatives

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_037

of benzene (aminobenzenesulfonic acid) or by their trivial names (metanilic acid for *m*-aminobenzenesulfonic acid). If two of the hydrogen atoms of ammonia are replaced by aryl groups, the compounds are generally described as diarylamines, with diphenylamine (DPA) as the parent compound. Aromatic amines with two amino groups on the same benzene ring are named phenylenedi-amines. *Chemical Abstracts* called these compounds benzenediamines in 1972.

Historical Development. In 1826 O. UNVERDORBEN first obtained aniline by the dry distillation of indigo and called it "krystallin". In 1834 F. RUNGE found it in coal tar; in 1841 C. F. FRITZSCHE prepared the same oily liquid by heating indigo with potash and gave it the name "aniline," from "anil" (the Portuguese word for indigo), which was identical to the "benzidam" of N. N. ZININ (1841). The structure was proved by A. W. VON HOFMANN in 1843, who showed that it was obtained from the reduction of nitrobenzene. This is still the most common method of production. Diphenylamine, the simplest diarylamine, was first prepared by VON HOFMANN in 1863 by destructive distillation of triphenylmethane dyes.

Major Uses and Importance. Analgesics and Antipyretics; Antioxidants; Azo Dyes; Chemotherapeutics; Fungicides, Agricultural; Insect Control; Optical Brighteners; Ozone; Photography; Pigments, Organic; Polyurethanes; Rubber 4., Chemicals and Additives; Weed Control are separate keywords.

Aromatic amines are widely used as dye intermediates, especially for azo dyes, pigments, and optical brighteners; as intermediates for photographic chemicals, pharmaceuticals, and agricultural chemicals; in polymers via isocyanates for polyurethanes; and as antioxidants. They have been listed as corrosion inhibitors of mild steel in the pickling process [1].

The oldest use of aromatic amines is as intermediates for *dyes*. Substituted anilines and especially naphthylamines have been precursors of azo dyes since the middle of the 1800s. Even with the replacement of the once predominant anthraquinone dyes with more and more azo dyes derived from aromatic amines, the previous strong demand of aniline in the dye industry has decreased markedly in the United States to less than 4 % of its former magnitude. Once over 700 dyes listed in the Colour Index (C. I.) [2] were prepared from aniline and its derivatives; now only a few are produced in commercial quantities.

The production and sales volume for the aniline derivatives as a group is generally growing only at the average rate of expansion of the chemical market as a whole. United States production of many of them has ceased, and the supply is shifting to Japan, Korea, China, and other East Asian countries along with textile and dye production.

p-Nitroaniline [*100-01-6*], with a United States production of 6200 t in 1981 [3] and an import volume of 630 t in 1983 [4], is probably the largest in this group. *p*-Nitroaniline is used mainly in the production of dyes, antioxidants, and pharmaceuticals.

Anisidines, especially *o*-anisidine [*90-04-0*], with a limited United States production and imports of 570 t in 1983 [4], is an important intermediate for pigments and azo dyes. Japan reported a production of only 320 t in 1981 [5], down from a high of 997 t in 1974. *Chloroanilines* are used mostly for agricultural products. *4,4′-Diamino-2,2′-stilbenedisulfonic acid* [*81-11-8*] has maintained its strength as the largest volume raw material for optical brighteners (United States use 5000 t in 1984).

By far the largest share of the *aniline* consumption (67 % of total 1984 consumption) is used for the manufacture of isocyanates, primarily for 4,4′-methylenebis(phenylisocyanate), (MDI) to make polyurethanes. About 20 % of the aniline consumption in the United States and in Western Europe versus 27 % in Japan is used in the rubber industry for the manufacture of antioxidants; vulcanization accelerators, such as 2-mercaptobenzothiazoles (MBT) [*149-30-4*]; diphenylguanidines; for condensation products of aniline with aldehydes and ketones, e.g., 2,2,4-trimethyl-1,2-dihydroquinoline (TMDHQ) [*147-47-7*] and its polymer [*26780-96-1*]. Many herbicides, fungicides, insecticides, and animal repellents are made from aniline or its derivatives. Between 1960 and 1980, United States aniline consumption grew at an average rate of 8.8 % annually and then slowed down to an average rate of 3.1 % in the period 1980 – 1984.From 1980 to 1993

aniline consumption grew from 0.29 to 0.49 Mio t in th United States, in Western Europe from 0.30 to 0.59 Mio t, and in Japan from 0.07 to 0.16 Mio t [6].

Analgesics and sulfonamides are examples of important pharmaceuticals derived from aromatic amines. Many sulfa drugs start from acetanilide (antifebrin) [*103-84-4*], which itself has been used as an antipyretic and analgesic agent.

Diarylamines readily donate their amine hydrogen atom to terminate various free-radical reactions. For this reason they are widely used as antioxidants for various polymers and elastomers, and as stabilizers for nitrocellulose [7]. Nearly all commercial synthetic rubbers are protected with alkylated diphenylamines. Because they darken on oxidation, diphenylamines cannot be used in light colored rubber and polymer compositions. In this case *N,N′*-di-β-naphthyl-*p*-phenylenediamines are used instead. Some diarylamines retard the effect of intense gamma or neutron radiation [8]. Diarylamines have been used to stabilize sulfur trioxide, are used as corrosion inhibitors in roofing asphalt, and are essential in promoting cross-linking in poly(vinyl chloride) [9] and in polyethylene [10]. Diarylamines containing other functional groups, such as amino or hydroxy, are used as dye intermediates [11], antiozonants, in color photography, and for hair dyeing and have been patented for use in the image formation process in photographic films [12], [13].

2. Physical and Chemical Properties

2.1. Physical Properties

All aromatic amines are either solids or liquids at room temperature. The ones without other functional groups are colorless, high-boiling materials having a characteristic odor. Most oxidize on exposure to air and darken. They are only slightly soluble in water.

In contrast to the aliphatic amines, which are stronger bases than ammonia, the aromatic amines are only weakly basic with basicity constants $K_B \leqq 10^{-10}$ in water. Their onium salts, therefore, are ionized in water and act as Brønsted acids.

The effect of the phenyl groups becomes even more dominant in diphenylamine ($K_B = 10^{-14}$), which can form salts only with strong acids that are completely ionized in water, whereas triphenylamine rarely forms salts and has no basic properties.

The physical properties of the most important aromatic amines are given under → Aniline.

2.2. Chemical Properties

The chemical reactions of aromatic amines are similar to those of aliphatic amines. These reactions are influenced greatly by the basicity of the amine nitrogen. Therefore, such electron-withdrawing substituents as nitro and cyano reduce the base strength of the amine nitrogen when substituted in the ortho or para positions of the benzene ring(s). Aromatic amines undergo a variety of chemical reactions. The ones of greatest industrial significance are described in this section.

2.2.1. Acetylation and Similar Reactions

Primary and secondary aromatic amines react with carboxylic acids, acid chlorides, anhydrides, and esters to form a wide variety of commercially important amides. For example, *p*-acetanisidine, *N*-(4-methoxyphenyl)acetamide [*51-66-1*], is obtained in nearly theoretical yield, especially if the water formed is removed (e.g., by distillation).

Acid chlorides, in general, give the best yields of pure product. Polymeric aromatic amides have been made from *m*- and *p*-phenylenediamines by reaction with iso- or terephthaloyl chloride. These so-called aramid fibers are marketed by Du Pont (United States) under the trade names Nomex, poly(1,3-phenyleneisophthalamide) [*24938-60-1*], and as Kevlar, poly(1,4-phenyleneterephthalamide) [*24938-64-5*] [14], [15] (→ Fibers, 4. Synthetic Organic).

The reaction with phosgene gives isocyanates or ureas depending on the reaction conditions.

Commercially important isocyanates are obtained from toluenediamine, methylenedianiline, and other aromatic primary diamines. The monoisocyanates are used in such agricultural products as herbicides, insecticides, bacteriostats, fungicides, and pesticides. The major use of the diisocyanates is as intermediates for polyurethanes.

Reaction with dimethylformamide in the presence of sodium methoxide yields *N*-arylformamides in 45 – 88 % yield [16], [17]. With aromatic aldehydes, Schiff bases (azomethines, Ar - CH = N - Ar′) are formed, and with chloral and hydroxylamine, oximinoacetanilides result in 80 – 91 % yield [18]. Dithiocarbamic acid ammonium salts are formed with CS_2 and NH_3 in toluene. These salts give aryl isothiocyanates (70 – 90 % yield) when treated with phosgene [19].

Instead of toluene, water also can be used as the solvent, followed by treatment with heavy metal salts, e.g., $Pb(NO_3)_2$, $CuSO_4$, $FeCl_3$ [20]. Using CS_2 alone in ethanol or acetone, aromatic amines react to yield *N,N′*-diarylthioureas.

With cyanogen chloride, *N,N*-diarylguanidines are formed in 90 % yield.

2.2.2. *N*-Alkylation and Condensations

Alkylation of aromatic amines to the corresponding *N*-alkyl- and *N,N*-dialkylamines is generally of importance only for aniline (→ Aniline), [21–24].

Substituted mono- or diethanolamines can be produced in high yields from ethylene or propylene oxide and an aromatic amine.

The resulting products, as such, or after further acetylation of the hydroxy groups, are important coupling compounds for azo dyes.

Aldehydes, ketones, acetals, and orthoformates give a variety of condensation products depending on the reaction conditions. For example the reaction of aromatic amines with ketones gives Schiff bases that can be hydrogenated to the alkyl-substituted amines. In the case of phenylenediamine derivatives, important antioxidants and antiozonants for rubber are produced, such as *N*-(1,3-dimethylbutyl)-*N′*-*p*-phenylenediamine [*793-24-8*], which is sold under various *trade names:* Vulkanox 4020 (Mobay, Bayer), Flexone 7L (Uniroyal), Santoflex 13 (Monsanto), UOP 588 (UOP), Wingstay 300 (Goodyear).

2.2.3. *C*-Alkylation

Under Friedel – Crafts conditions, the aromatic ring can be alkylated with alkenes to form the corresponding alkylanilines at temperatures of 200 – 280 °C and 20 MPa (200 bar). The alkylation takes place in the positions ortho to the amino group and if one is occupied only monoalkylation results [25–29].

These compounds are used as chain extenders for polyurethanes (e.g., 3,5-diethyl-2,4-diaminotoluene), and for herbicides (e.g., 2,6-diethylaniline and 2-methyl-6-ethylaniline).

2.2.4. Cyclization

Aromatic amines undergo numerous cyclization reactions to give a variety of *N*-heterocyclic

compounds. Quinoline derivatives are obtained with aldehydes and ketones. Aniline condenses with acetone in the presence of hydrochloric acid, *p*-toluenesulfonic acid, acidic clays, or acidic ion-exchange resins to give 2,2,4-trimethyl-1,2-dihydroquinoline (TMDHQ) [*147-47-7*], which on oligomerization is used as an antioxidant in the rubber industry.

With aldehydes and styrenes, 1,2,3,4-tetrahydroquinolines result [30], and with glycerol or acrolein, quinoline [*91-22-5*] is formed in the Skraup synthesis [31]. Many of the substituted quinolines are intermediates for antimalarial agents. In the Combes quinoline synthesis [32], aniline and 1,3-diketones are condensed to make 2,4-disubstituted quinolines. With hydroxyketones or with haloketones, aromatic amines yield substituted indoles [33]. Aromatic amines and 2-aminophenols condense with CS_2 to form 2-mercapto-1,3-benzothiazole. With sulfur monochloride (S_2Cl_2) 1,2,3-benzodithiazole is formed and can be hydrolyzed to the corresponding 2-aminothiophenol in yields of up to 93 % [34].

Benzofuroxane [*480-96-6*] results from the treatment of *o*-nitroaniline with sodium hypochlorite [35].

Diphenylamines form carbazoles when heated with iodine as the catalyst, whereas heating diphenylamine with sulfur in the presence of various catalysts results in phenothiazine [*92-84-2*].

2.2.5. Diazotization

Primary aromatic amines react with nitrous acid to form diazonium salts.

This reaction has considerable general utility and forms the basis for azo dye production by coupling of the diazonium salt with aromatic amines and phenols (→ Azo Dyes). In the Sandmeyer reaction the diazo group is replaced by chlorine from a CuCl solution. The reaction also is used for the introduction of Br, CN, I, and sometimes also aryl and alkyl groups. Secondary aromatic amines react with nitrous acid to form *N*-nitroso compounds in the same way as do aliphatic amines.

Tertiary aromatic amines do not give *N*-nitroso compounds but undergo *C*-nitrozation.

Diaryldiazenes are obtained by the oxidation of aromatic amines with $KMnO_4$ in aqueous KOH [36] or by the reaction of aromatic amines with aromatic nitrosamines [37].

$$Ar-NO + H_2N-Ar' \xrightarrow[70-95\%]{CH_3COOH} Ar-N=N-Ar' + H_2O$$

o-Phenylenediamines react with nitrite at neutral to slightly acidic pH to undergo ring closure to the corresponding benzotriazoles [38], [39]; these are important corrosion inhibitors for Cu-containing alloys.

2.2.6. Halogenation

The chlorination of aniline salts in aqueous solutions is so fast that only the trichloroaniline can be isolated [40]. Chlorine in the presence of hydrogen chloride in an anhydrous solvent yields 2,4,6-trichloroaniline [*634-93-5*] [41]. In aqueous sulfuric acid at 110 °C aniline gives chloranil, 2,3,5,6-tetrachloro-2,5-cyclohexadiene-1,4-dione [*118-75-2*], in 91 % yield [42].

2.2.7. Nitration

Generally, nitration of aromatic amines with nitric acid results in concomitant oxidation of the amino function. If it is protected, predominantly the para- and ortho-nitro isomers are formed. Nitration of *p*-acetanisidine [*51-66-1*] in sulfuric acid yields 2-nitro-4-acetaminoanisole [*50651-39-3*] as the major product. This compound can be hydrolyzed subsequently to the free amine.

The nitration of *p*-acetaminotoluene [*103-89-9*], however, leads predominantly to substitution ortho to the acetamino group.

2.2.8. Oxidation

Aromatic amines are very susceptible to oxidation and most turn brown or black if exposed to air for extended periods. The course of oxidation depends on the nature of the oxidizing agent. With hydrogen peroxide and percarboxylic acids (e.g., peracetic acid), oxidation to the corresponding *N*-phenylhydroxylamine or to nitroso or nitrobenzene may occur, depending on temperature and the amount of oxidizing agent present [43]. 2,6-Dichloroaniline [*608-31-1*] is oxidized to 2,6-dichloronitrobenzene by trifluoroperacetic acid [44].

Oxidation with MnO_2 or $Na_2Cr_2O_7$ in sulfuric acid leads to quinones; e.g., 1-naphthylamine is oxidized to 1,4-naphthoquinone. Oxidation of aniline with dichromate or chlorate in the presence of copper or vanadium yields aniline black.

2.2.9. Sulfonation

Reaction of aromatic amines with sulfuric acid, oleum, or sulfur trioxide leads to the introduction of the sulfonic acid group mainly in the positions ortho or para to the amino group. 2-Methoxy-5-methylaniline [*120-71-8*] is sulfonated with fuming sulfuric acid to 4-amino-5-methoxy-2-methylbenzenesulfonic acid [*6471-78-9*] (the intermediate to make the dye FD & C Red 40 [*25956-17-6*] [2]).

1-Naphthylamine [*134-32-7*] is sulfonated with oleum at room temperature to give 1-amino-4- [*84-86-6*] and 5-naphthalenesulfonic acid [*84-89-9*].

Many aromatic amines also sulfonate via the *baking process* in which the amine sulfate is heated to 220 °C under vacuum to yield either the *para*- or *ortho*-sulfonic acid. The process is very selective and gives high yields of the *p*-sulfonic acid, e.g., aniline leads to sulfanilic acid (4-aminobenzenesulfonic acid [*121-57-3*]). If the para position is occupied, sulfonation takes place ortho to the amino group; e.g., *p*-toluidine [*106-49-0*] gives 2-amino-5-methylbenzenesulfonic acid [*88-44-8*] [45]. 1-Naphthylamine yields only 1-amino-4-naphthalenesulfonic acid [*84-86-6*], also known as naphthionic acid [11]. This compound is used as a dye intermediate for Congo Red, Fast Red A, Azo Rubin, and others.

2.2.10. Reduction

Hydrogenation of aromatic amines results in the corresponding cycloaliphatic amines. This process is of greatest importance with amines that do not contain other easily reducible functional groups. Such catalysts as Raney nickel, cobalt – alumina, and more exotic ones are used [46]. Hydrogenation of aniline using an alumina–silicate catalyst [47] leads to 80 % cyclohexyl-amine [*108-91-8*] and 15 % dicylohexylamine [*101-83-7*]; bis(4-amino-3-methylphenyl)methane is reduced in 89 % yield on an alumina catalyst [48]. Hydrogenation of aniline over a Raney nickel catalyst gives 95 % dicyclohexylamine [49]. Good results have been obtained with rhodium catalysts. 4,4′-Methylenedianiline (MDA) [*101-77-9*] has been hydrogenated on a 5 % rhodium – aluminum catalyst to give bis(4-aminocyclohexyl)methane in good yield [48].

2.2.11. Other Reactions

In a reversal of the Bucherer reaction, naphthylamines can be hydrolyzed to the corresponding naphthol in yields approaching 100 %. Sulfonic acid groups on the ring accelerate the reaction [50], [51].

3. Production

Generally, three types of reactions are used for the production of aromatic amines:

1) *Reductions:* using such metals as Fe, Zn, Sn, and Al or their salts; sulfur compounds; electrochemical methods; and catalytic hydrogenation
2) *Nucleophilic substitutions:* replacement of such substituents as halogen, hydroxyl, alkoxy, and sulfo groups
3) *Rearrangements and degradations:* including the benzidine and Beckmann rearrangements, and the Schmidt and Hofmann degradations.

Only the first two reaction types are of general importance. Chemical rearrangements and degradations seldom lead to clean reaction products in high yield.

3.1. Reduction

All aromatic carbon – nitrogen compounds with nitrogen oxidation numbers $\geqq -2$ can be reduced to aromatic amines (for a summary see [52]). Only the reduction of nitro compounds has gained widespread industrial acceptance, be-cause the starting materials can be prepared with a high degree of specificity for a wide variety of compounds. Other aromatic nitrogen compounds cannot be produced economically enough to be used as starting materials for aromatic amines.

3.1.1. Chemical Reduction

In the chemical reduction of aromatic nitro compounds to aromatic amines, the hydrogen that becomes attached to the nitrogen normally comes from the solvent, in many cases water, or from the added acid. The most important reductants are metals, such as iron, tin, and zinc; phosphorus, sulfides, sulfites, and sulfur dioxide are used also. Because oxidation of the reducing agent may result in a useless waste product, which has to be removed in an environmentally safe way, chemical reduction has lost its importance in favor of catalytic reduction for the large-scale production of products.

Reduction with Iron. The reduction with iron in dilute acid was described by Béchamp in 1854 and the process still carries his name. Iron is still the most important metal for the reduction of nitro compounds to aromatic amines, and generally, all nitro compounds can be reduced to the corresponding aromatic amines with iron in water and acid. Side products are expected only if the molecule contains other substituents that can be reduced easily (e.g., nitroso, azo, hydrazine, sulfoxide, and other nitro groups) or can be saponified [52]. Carbon – carbon multiple bonds are not attacked. Bayer (Germany) and Mobay (United States) both use this iron

reduction for the production of iron oxides with aniline as the resulting side product. For a further discussion, → Aniline, Section 2.3, and [52–55].

Another example of industrial importance is the reduction of 4,4′-dinitro-2,2′-stilbenedisulfonic acid to 4,4′-diamino-2,2′-stilbenedisulfonic acid [*81-11-8*], which is still done exclusively using iron in neutral medium. Also, many small-volume dye intermediates are reduced with iron.

Reduction with Other Metals. Aromatic nitro groups also can be reduced with zinc, tin, and aluminum, or their salts in acidic, neutral, or alkaline medium [52].

These reducing agents are generally very mild and do not interfere with, e.g.,-OH, -OR, -COOH, -CO-Ar, halogen, or -CN groups. However, except for laboratory applications they are not of any industrial significance. Instead, catalytic hydrogenation is used because of waste water regulations.

Reductions with Sulfide, Hydrogensulfite, and Sulfur Dioxide. Compounds with several nitro groups can be reduced to nitro amines if a stoichiometric amount of *sulfide* is used [56], [57]. In this case, sodium or ammonium sulfide is the reagent of choice. *m*-Nitroaniline [*99-09-2*] can be obtained in 87 % yield from 1,3-dinitrobenzene [56]:

The addition of sulfur reduces the required amount of sodium sulfide. 4-Nitrotoluene is reduced nearly quantitatively to 4-aminobenzaldehyde [*556-18-3*] with sodium sulfide and sulfur [58], [59].

Azo groups stay unchanged if the reduction with sodium sulfide is carried out at 40 – 70 °C, if the reaction times are kept short, and if sulfide is not in excess. However, halogen substituents are replaced easily by -SH [56], [57]. When excess reducing agent is not a problem, ammonium hydrogensulfide in the presence of ammonia can be used [57], [60].

The reduction of aromatic nitro, nitroso, or azo compounds with *sulfite* or *hydrogensulfite* to the corresponding aromatic amines is known as the Piria reaction (Piria, 1851). In aqueous or alcoholic medium, mainly *N*- and *C*-sulfonic acids result [61]. On treatment of these with mineral acid, a mixture of aromatic amines and aminobenzenesulfonic acids is formed.

The quinone oxime intermediate facilitates substitution of hydrogensulfite onto the aromatic ring in the reduction of *ortho*- and *para*-nitrosophenols or naphthols:

If the hydroxyl group is in the para position, the sulfo group will enter in the 2 – position. Substituents in the 3 – position (e.g., Cl or COOH) are replaced by H [62].

Only after methods were found to reduce the amount of *C*-sulfonation did reduction with SO_2 gain industrial importance. This reduction is best carried out in a closed system in strongly acidic media (e.g., 15 – 40 % aqueous sulfuric acid) at temperatures of 80 – 180 °C with iodine, hydrogen iodide, or iodine salts as catalysts. Glass-lined reactors are the best [63].

Sodium dithionite reduces the aromatic nitro and nitroso group nearly quantitatively [64]:

When possible, reductions with sulfide, sulfite, and other sulfur compounds have been replaced by catalytic hydrogenations, resulting in cleaner reaction mixtures, less corrosion (resulting when SO_2 is used), and fewer environmental problems.

Electrochemical Reduction of Nitro Compounds. Electrochemical reduction is generally

a special case of the chemical reduction. An inorganic compound is used as the reducing agent; the oxidized form is then reduced at the cathode and can react again.

The cathode is made of Pb, Sn, Ni, or Cu, and 15 – 20 % hydrochloric acid is used on the cathode side of a semi-permeable membrane. On the anode side 30 % sulfuric acid is employed [65].

Although electrochemical reductions have been known for more than 100 years, they have remained mostly curiosities and have not been used commercially to any great extent in the past. However, interest is growing as better cells and membranes become available. Some products have been produced electrochemically, especially in India; e.g., *p*-aminobenzoic acid [*150-13-0*], *p*-aminophenol [*123-30-8*], and many others have reached pilot-plant scale or beyond [66], [67].

3.1.2. Catalytic Hydrogenation

Reduction with Hydrazine. The reduction of aromatic nitro compounds with hydrazine represents, in most cases, a special variation of catalytic hydrogenation, where hydrazine is the source of the hydrogen. The mechanism of decomposition of hydrazine on precious-metal catalysts differs depending on the pH value, with the amount of hydrogen generated per mole of hydrazine increasing with higher pH [68]. At weakly alkaline or neutral conditions, 1 mol H_2 is generated:

$$3\,N_2H_4 \xrightarrow{\text{Pt, Pd, or Ni}} 2\,NH_3 + 2\,N_2 + 3\,H_2$$

If barium hydroxide or calcium carbonate is added, 2 mol of H_2 are formed:

$$N_2H_4 \xrightarrow{\text{Pd or Pt}} N_2 + 2\,H_2$$

The reduction with hydrazine sometimes occurs without a catalyst but in most cases is done in the presence of a hydrogenation catalyst, such as Raney nickel, Pd on carbon, or Pd on $CaCO_3$ [69], [70]. Ideally 1 mol of hydrazine gives four reduction equivalents depending on the pH and catalyst, but in practice fewer are formed, and an excess of hydrazine must be used. Carbon – carbon double bonds and carbonyl groups are not attacked [71]. Depending on the reaction conditions, the intermediates of the reduction can be isolated.

In the reduction using hydrazine without a catalyst, carbonyl-containing compounds are reduced to the corresponding hydroxy compounds via the hydrazone intermediate [72]. The reduction of aromatic nitro compounds with hydrazine has no advantage over catalytic reduction with much cheaper hydrogen, except for laboratory work and very small product volumes, where it allows use of normal pressure. Examples of catalytic reduction with hydrazine hydrate on Pd / C and on Raney nickel can be found in [70], [73–75].

Cyclohexene also has been used on a laboratory scale as a hydrogen source for the catalytic hydrogenation of polynitro compounds [76].

Reduction with Hydrogen. Primary aromatic mono- or polyamines generally are produced by the catalytic hydrogenation of the corresponding nitro compound, either in the vapor or in the liquid phase, with or without a solvent [46], [77–79]. All large-scale products, such as aniline (→ Aniline), or *o*- and *p*-toluidine (→ Toluidines), 2,4- and 2,6-diaminotoluene (→ Phenylenediamines and Toluenediamines), and 1-naphthylamine (→ Naphthalene Derivatives), are produced in this way. For the reaction meachanism see [80], [81].

Catalytic reduction of nitro compounds is very exothermic. In the hydrogenation of nitrobenzene in the liquid phase, 553.5 kJ/mol are released, whereas hydrogenation in the vapor

phase at 200 °C releases 493.2 kJ/mol. Unless this heat is dissipated properly, explosions can result, especially if thermal decomposition of the nitro compound occurs or condensation reactions are initiated as with chloro – nitro compounds [52]. To reduce these hazards, the concentration of nitro compound, the amount and partial pressure of hydrogen, the temperature, and the activity of the catalyst are controlled.

Vapor-Phase Hydrogenation. Industrial use of vapor-phase hydrogenation is limited by the boiling point and the thermal stability of the nitro compounds. Most aniline produced in the United States is made by vapor-phase hydrogenation of nitrobenzene over copper – silica catalyst in $\geqq$ 99 % yield, whereas Pd – alumina is used by Bayer in Europe and Brazil.

Liquid-Phase Hydrogenation. It is preferable to hydrogenate most aromatic nitro compounds in the liquid phase. In this case the pressure and temperature can be changed independently. The temperature is limited by the hydrogenation reaction of the aromatic ring which occurs above 170 – 200 °C. Normally the reduction is carried out at 100 – 170 °C. Some compounds (e.g., 1-bromo-4-nitrobenzene) must be hydrogenated at lower temperatures (20 – 70 °C) to avoid cleavage of sensitive groups. Pressures of 1 – 15 MPa (10 – 150 bar) are used industrially. For the hydrogenation of sensitive nitro aromatic compounds lower pressures are advisable (0.1 – 5 MPa, 1 – 50 bar) [82–84]. Generally the pressure only influences the speed of the reaction by increasing the phase transfer and saturation of the catalyst with hydrogen. The reaction time depends on many parameters, such as hydrogen pressure, concentration, temperature, activity and concentration of the catalyst, and mixing. Often an induction period is observed, which is independent of the activity of the catalyst [85], [86]. Generally the reaction time is from a few minutes to several hours. Considerably longer times are necessary if these parameters are not optimized.

Because of the exothermic nature of the reaction, many safety precautions must be observed, especially for the industrial hydrogenation of aromatic polynitro compounds in the liquid phase without solvents [87–89]. The exothermic reaction is controlled by the continuous addition of small quantities of the nitro compound, thus keeping its concentration below 2 % [90]. Deionized water can be added to remove the heat of reaction by continuous evaporation. The water also affects the activity of the catalyst; e.g., the more water present in the batch hydrogenation of dinitrotoluene without solvent, the lower the activity of the Pd on carbon catalyst [91], [92]. If the amine shows good water solubility, water can be used as the solvent. Water also can be used in cases where the nitro compound forms water-soluble salts with alkali, such as with nitrocarbonic or sulfonic acids. Sometimes 30 – 40 % solutions of the amine in water can be produced directly in the hydrogenation reactor without an additional concentration step [52], [93].

Solvents. Methanol and 2-propanol are preferred; also dioxane, tetrahydrofuran, and *N*-methylpyrrolidone have been used; e.g., *o*-nitrophenol is hydrogenated in good yields in methanol with Pt on carbon. The concentration of the nitro compound can vary substantially. According to [94] a 33 wt% solution of dinitrotoluene in methanol is fed into the hydrogenation reactor, whereas Olin recommends a 15 – 35 wt% solution [95]. In the hydrogenation with a water-immiscible solvent, such as toluene, the water must be removed, as in solvent-free hydrogenation, in order to maintain the activity of the catalyst. Very polar nitro compounds, e.g., bis(4-amino-3-nitrophenyl)sulfone, are hydrogenated in liquid ammonia [96].

Hydrogenation Catalysts. For vapor-phase hydrogenation only metals or metal derivatives on supports are used in fixed beds or fluidized beds, whereas metals with large surfaces (Raney nickel) or metals and metal derivatives on supports with large surfaces (carbon, alumina) are used for the liquid-phase hydrogenation. In practice only Raney nickel, Raney nickel – iron, Raney cobalt, and Raney copper are used as pure-metal catalysts because of their relatively low cost. Precious-metal catalysts, such as Pt and Pd, generally are used at concentrations of 0.5 – 5 wt% on support material with large surfaces, such as charcoal, silica, aluminum oxide, or alkaline-earth carbonates. The powdered form of the catalyst is used in slurries and the pellet form in fixed beds [97]. Because the support material may activate or deactivate the catalyst [81], it is important to find the optimum conditions that not only allow the catalyst to

be used repeatedly and to be regenerated but also are economical for large-scale (> 500 t/a) products [88], [98]. Decomposition and oxidation products generally deactivate catalysts by blocking the active surfaces [81]. Even in small quantities, compounds containing sulfur, arsenic, or antimony are catalyst poisons. However, with increased oxidation state (e.g., $As^{3-} \rightarrow As^{5+}$ or $S^{2-} \rightarrow S^{4+}$) these compounds have less effect as catalyst poisons. With noble metal catalysts, such ions as halide, sodium, and magnesium, cobalt metal, and CO_2 reduce the activity. Nitro aromatic compounds containing sulfur are better reduced with molybdenum or tungsten sulfide [99], or with nickel catalysts that contain zinc or calcium carbonate [102]. In the hydrogenation with Pd on carbon, copper salts are catalyst poisons, whereas in the hydrogenation of dinitrotoluene, both nitrophenol and nitrocresol are strong catalyst poisons and decomposition activators [46], [101].

Hydrogenation of Halide-Substituted Nitro Compounds. Whereas most aromatic nitro compounds are hydrogenated at 100 – 170 °C, lower temperatures are used with halogen-substituted nitro compounds to avoid halide – hydrogen exchange. The catalysts have reduced activity, e.g., sulfide-poisoned metal catalysts. 1-Chloro 2 – nitrobenzene can be reduced at 80 °C and 1.0 – 5.0 MPa (10 – 50 bar) with a 5 wt% Pt on carbon catalyst, which is treated at 22 °C with dilute sulfuric acid, then with H_2 followed by H_2S [102]. The catalyst can be recycled up to 30 times without any further purification. The reaction time is 30 min per batch and only 0.1 % chlorine is cleaved. Therefore, a product of high purity and stability can be obtained in nearly quantitative yield. Also 3-chloroaniline [*108-42-9*], 4-chloroaniline [*106-47-8*], 2,5-dichloroaniline [*95-82-9*], 3,4-dichloroaniline [*95-76-1*], 2,6-dichloroaniline [*608-31-1*], 6-chloro-2-aminotoluene [*87-60-5*], and 4-chloro-2-aminotoluene [*95-79-4*] can be prepared in high yield and purity by this method.

A similar sulfide-poisoned catalyst has been described [103], in which 5 % platinum on carbon catalyst was treated with 1 % aqueous sulfuric acid, hydrogen, and sodium sulfide solution. 2,5-Dichloronitrobenzene was hydrogenated with this catalyst at 90 – 100 °C, 1.0 – 3.0 MPa (10 – 30 bar), 40 min per batch. The catalyst was recycled at least 30 times without loss of activity or selectivity while chlorine cleavage was kept $\leqq$ 0.1 %; yield of 2,5-dichloroaniline [*95-82-9*] was 97 %. Also a 1 % Pt on carbon catalyst was treated with dimethylsulfoxide in water before it was used in the hydrogenation of chloronitro aromatic compounds in 98.4 % yield [104]. Additional treatment with hydrazine hydrate increased the activity of the catalyst with yields of 99.6 % for 2-chloroaniline [*95-51-2*]. Modification of Pt on carbon with lead, bismuth, or silver salts for the hydrogenation of chloronitrobenzene at 100 °C gave chloroaniline in 99 % yield, whereas untreated catalyst at 77 °C resulted in 100 % hydrolysis [105]. 3-Bromonitrobenzene has been hydrogenated using Pt on barium or strontium carbonate at 20 °C, 0.1 MPa (1 bar) [106]. The catalytic activity of Raney nickel can be modified also. For the hydrogenation of 3-chloronitrobenzene the addition of 0.1 – 20 % of thiocyanate to the catalyst has proved beneficial [84].

Equipment and Construction Materials. Hydrogenation in the vapor phase is carried out only continuously, but in the liquid phase it can be done in batch or continuous operation de-pending on volume. Continuous liquid-phase hydrogenation is used exclusively for a relatively few large-scale products, such as dinitrotoluene, nitrotoluene, and 1-nitronaphthalene [92]. The vast majority of aromatic amines have small annual volumes (< 500 t) and are produced by batch hydrogenation with catalyst slurries. This allows fast changeover from one product to another, which is not possible when fixed-bed catalysts are used. The intensive mixing of the three phases (hydrogen gas, nitro compound solution, and solid catalyst) is of great importance. The transport of the reactants toward the active centers of the catalyst, and of the products away from them, must be rapid for good reaction.

Although batch catalytic hydrogenations traditionally are done in stirred, steel or stainless steel autoclaves (Fig. 1), improvements in performance are being realized increasingly through loop reactor technology. Production units employing the loop reactor principle (Fig. 2) have been available for the last two decades and have been applied successfully to the catalytic hydrogenation of aromatic nitro compounds by Buss (Basel, Switzerland) [107–110]. The major advantages reported over stirred autoclaves are increased heat and mass trans-

fers and improved reaction selectivity. In continuous hydrogenation, generally shorter batch cycle times and higher product yields result. In addition catalyst usage is often lower.

The basic operating principle of a loop reactor is shown in Figure 3 [107–110]. The batch charge and slurry-type catalyst are pumped continuously through an external heat exchanger to a mixing nozzle in the top head of the autoclave. The nozzle acts as an eductor, and the action of the slurry passing through it creates intimate gas – liquid – solid mixing. The chemical reaction primarily takes place in a well-defined zone inside the nozzle prior to gas – liquid disengagement at the nozzle exit. The autoclave acts as a holding vessel. A loop reactor allows for simple and reliable transfer from pilot plant to production, because the scaleup is based only on the nozzle configuration and pump-around rate. In the case of a stirred autoclave, scaleup is more difficult because of the ratio between a small pilot vessel and a large production vessel (e.g., 1 : 1500 to 1 : 12500). Temperature and concentration gradients as well as longer reaction times in the production vessel often result in undesired side reactions and a decreased product yield. Loop reactors minimize these problems by limiting the reaction to a highly agitated, well-defined zone, with a considerably decreased cycle time.

3.2. Nucleophilic Substitution

Practically all non-carbon substituents on the aromatic ring can be exchanged for amino groups. However, only a few of these substitution reactions are of industrial importance, including:

1) Exchange of halide
2) Exchange of hydroxyl and ether groups
3) Exchange of sulfo groups

Figure 3. Operating principle of a loop reactor
a) Autoclave; b) Mixing and reaction zone; c) Reactant, solvent, catalyst suspension; d) Flow; e) Primary loop recirculation pump; f) Primary loop heat exchanger

3.2.1. Exchange of Halide

Exchange of halide is universally useful for the production of amines with mono-, poly-, or heterocyclic substituents as well as for diaryl-amines [111–113], and arylpolyamines [114], [115]. Many of the products are used as dye or pigment intermediates. The substitution of a halide on the aromatic ring with ammonia or with amines occurs via two different mechanisms, depending on whether the halide is activated or unactivated.

3.2.1.1. Activated Halides

Aromatic halides containing ortho and/or para electron-withdrawing substituents, e.g., $-NO_2$ or $-CN$, undergo nucleophilic aromatic substitution [116], [117]. Both *o*- and *p*-chloronitrobenzene react with ammonia at 170 °C, whereas 2,4-dinitrochlorobenzene requires only 70 °C and no catalyst [118], [119].

The more basic the amine (unless it is sterically hindered), the faster the reaction with the haloaromatic compound. In the reaction of methylamine and ammonia with a solution or suspension of 2,4-dinitrochlorobenzene at higher temperature, good yields of *N*-methyl-2,4-dinitroaniline are obtained, rather than 2,4-dinitroaniline [120].

Reaction Conditions. *4-Nitroaniline* [*100-01-6*] is produced in an agitated titanium reactor in 99.3 % yield by reacting 4-chloronitrobenzene [*100-00-5*] with a tenfold excess of aqueous ammonia at 175 °C and 4.2 MPa (42 bar) for 10 h [121].

4-(4-Methylanilino)—3-nitrobenzenesulfonamide

is prepared in 90.1 % yield by heating 4-chloro-3-nitrobenzenesulfonamide and *p*-toluidine [*106-49-0*] for 5 h at 130 °C [111]. 4-Nitrodiphenylamine [*836-30-6*] (precursor for antiozonants for rubber) is made by the condensation of 4-nitrochlorobenzene with aniline in chlorobenzene. *N*-Alkylated *p*-phenylenediamine derivatives, however, cannot be produced in aqueous medium.

3.2.1.2. Unactivated Halides

Unactivated halides undergo elimination – addition reaction through a benzyne intermediate. This requires higher temperatures than nucleophilic aromatic substitution and results in isomeric mixtures if other substituents are present. The industrial usefulness of this reaction is therefore limited.

Chlorobenzene and ammonia react at a reasonable rate only above 200 °C [122], generally with the addition of a catalyst, such as copper(I) and copper(II) salts or their amine complexes [115], [123], [124]. Also metal amides (e.g., $NaNH_2$, $LiNEt_2$) are used. The energy needed to exchange the halide is the reverse of the order for activated halides: $F \gg Cl \gg Br > I$

Reaction Conditions. The reaction is generally carried out in aqueous suspension or in solution at elevated temperature and pressure. Because the reaction of arylhalides with amines is exothermic, it is especially important in the batch process to watch the temperature while heating to reaction conditions. This normally poses no problem in the continuous reaction. The hydrogen halide released during the reaction is neutralized either by excess ammonia or by the addition of bases, such as sodium carbonate or calcium oxide [113]. With excess amine the reaction generally proceeds with nearly quantitative yield. With an insufficient excess of strongly basic amines in aqueous solution, side reactions such as hydrolysis or the formation of diarylamines, can occur. Cyano groups are hydrolyzed to amides in aqueous solution, but this reaction can be avoided by using an inert solvent. Carboxylic acids are converted easily to the corresponding amide by reaction in nonaqueous media.

Material of Construction. The presence of halides and amines at elevated temperature and pressure can cause severe corrosion; therefore, the selection of materials and equipment becomes difficult. Autoclaves of normal steel can be used for laboratory work, but considerable reduction in the wall thickness must be expected (several millimeters per year). In addition, stress corrosion can lead to much faster deterioration of the reactor. Low-alloy steels are not useful for production units, especially with continuous working reactors. Stainless steels (chromium- and nickel-containing austenitic steels of the 316 types) were used with success for reactions in aqueous media. Because even these materials become pitted, other more corrosion-resistant alloys, such as Hastelloy and Inconel, have come into use. In addition, zirconium, titanium, and tantaclad (explosion clad tantalum on steel) have been used as reactor materials [121].

3.2.2. Exchange of Hydroxyl and Ether Groups

The displacement of an aromatic hydroxyl group by an amine is not only possible with phenols and cresols but also with quinoline and isoquinoline derivatives. In addition ammonia can replace alkoxy groups that are activated by nitro, halo, or cyano in the ortho or para positions. For example, 2,4-dinitroanisole [*119-27-7*] reacts with ammonia at 50 – 200 °C to form 2,4-dinitroaniline [*97-02-9*] in 50 – 90 % yield [125]. Interest in the reaction of phenols with amines is often a function of the cost of the phenol raw material. The principal exchange processes are:

1) *Reaction in aqueous medium without a catalyst.* 3-Nitrosalicylic acid reacts with aqueous ammonia at increased temperature and pressure to yield 2-amino-3-nitrobenzoic acid [126].
2) *Reaction in the presence of an acid catalyst.* *m*-Aminophenols are produced in the reaction of resorcinol [*108-46-3*] and aqueous ammonium hydroxide or alkylamines with boric acid as the catalyst [127]. Under anhydrous conditions with the same catalyst, 3-(β- and γ-hydroxyalkylamino)phenols are obtained from resorcinol and ethanolamine or 3-amino-1 – propanol [128]. A similar process uses an acid activated alumina – silica catalyst [129].
3) *In a multiphase system*, nitrophenols and ammonia react to yield nitroanilines, preferably using a solvent in which the reaction product has good solubility [130]. Many of the new phase-transfer catalysts are being applied to these reactions.
4) *p-Nitrosoaniline* and *p*-nitroso-*N*-phenylaniline [*156-10-5*] have been produced in liquid ammonia in the presence of either an ammonium salt or a tertiary amine, respectively, and an organic solvent [131].
5) *p-Nitrosophenols* are reacted with alkylamines via the *p*-nitrosophenylethers to give the corresponding *N*-substituted *p*-nitrosoanilines. The water that is eliminated in this process must be removed to drive the reaction to completion [132].
6) *The Halcon process* is the industrially important vapor-phase amination of phenol [133], [134]. Phenols or naphthols react in the gas phase with ammonia at 250 °C on metallic or nonmetallic oxides, e.g., MgO, B_2O_3, Al_2O_3, SiO_2, TiO_2, or mixtures of these. The Halcon process has been used by U.S. Steel Chemicals since 1982 in its plant at Haverhil, Ohio for the production of aniline from phenol (aniline capacity 100000 t/a) [135].
7) *The Bucherer reaction* is the reaction of 1- or 2-naphthols with aqueous amine or ammonium solutions using hydrogen sulfite as the catalyst. It is nearly exclusively used for the naphthalene series [116]. The use of hydrogensulfite reduces the reaction temperature by 50 – 150 °C and results in high yield (85 – 95 %) and purity. The reaction mechanism has been elucidated [136].

3.2.3. Exchange of Sulfo Groups

Ammonia can replace the sulfo groups in benzene, naphthalene, and anthraquinone derivatives. However, only in the anthraquinone series is this exchange of industrial importance (→ Anthraquinone Dyes and Intermediates). Until recently 1-aminoanthraquinones were made by reaction of 1-sulfoanthraquinones with amines. To destroy the released hydrogensulfite, stoichiometric amounts of an oxidizing agent, e.g., sodium 3-nitrobenzenesulfonate, were added. Increasingly 1-aminoanthraquinone [*82-45-1*] is made by reduction of the corresponding nitroanthraquinone. This method avoids the mercury-catalyzed sulfonation to the 1-sulfoanthraquinone. 1-Cyclohexylaminoanthraquinone-5-sulfonic acid is obtained from anthraquinone-1,5-disulfonic acid and cyclohexyl-amine in aqueous medium under pressure at 100 – 200 °C [138]. The hydrogensulfite is oxidized with sodium perchlorate or 3-nitrobenzenesulfonic acid.

3.3. Other Processes

Only a few of all other possible methods for the production of aromatic amines described in the literature should be mentioned here. 4,4′-Methylenedianiline is produced on a large scale by condensation of aniline with formaldehyde in aqueous or aqueous – methanolic solution. Diphenylamine is made by vapor-phase condensation of aniline over alumina or titanium catalyst at 450 – 500 °C [139] or in the liquid phase at 175 – 450 °C [140]. The rearrangement of arylhydroxylamines in dilute sulfuric acid leads to *o*- and *p*-aminophenols [141]. 3,3′-Dichlorobenzidine [*91-94-1*], an important pigment intermediate, is produced by Bofors (plant in Muskegan, MI) using the benzidine rearrangement starting from *o*-chloronitrobenzene.

4. Economic Aspects

The economically most important aromatic amines are discussed in separate keywords. For the others, data are generally unavailable.

5. Toxicology, Occupational Health, and Environmental Protection

5.1. Toxicity

The toxicity of aromatic amines has long been of concern to the chemical industry because of the serious nature of both acute and chronic effects of exposure to aromatic amines. Despite this, the toxicology of many of the individual compounds has not been studied thoroughly. Therefore, a discussion of aromatic amine toxicity in general is more appropriate than a discussion of individual compounds.

The primary hazards associated with aromatic amine exposure are methemoglobinemia and carcinogenesis. Both of these effects are attributed to activation products of metabolic *N*-oxidation [142]. Acute exposure, from either inhalation or skin contact, results in anoxia because of an impairment of the oxygen transport system of the blood. In aromatic amine exposure the heme iron of hemoglobin is oxidized from Fe(II) to Fe(III). The resulting product, methemoglobin, cannot combine with oxygen or carbon monoxide. The development of *methemoglobinemia* after exposure is often insidious; i.e., the onset of symptoms may be delayed for hours. Usually the first symptom is headache; anoxia, including cyanosis of lips, nose, and earlobes, develops when the methemoglobin blood level reaches 15 %. At levels of 40 %, weakness and dizziness are experienced, and at $>$ 70 %, coma and death may occur.

The extent to which various aromatic amines can cause methemoglobin formation varies widely. However, the arylhydroxylamines are recognized as the strongest methemoglobin formers in this group. The reason for their potency is that they are involved in a cyclic reaction. Phenylhydroxylamine reacts with hemoglobin to form methemoglobin and nitrosobenzene [143]. Nitrosobenzene is then reduced back to phenylhydroxylamine, which then is available to oxidize more hemoglobin. A small amount of nitrosobenzene appears to be reduced all the way to its amine, which eventually stops the reaction. As much as 50 mmol of methemoglobin may be produced by 1 mmol of hydroxylamine [144].

Figure 4. Examples of carcinogenic amines

The *carcinogenic potential* of aromatic amines is of greatest concern. A number of them are known or are suspected of being carcinogens. Indeed it has been reported that the epidemiology of aromatic amine carcinogenesis is essentially the epidemiology of human cancer of industrial origin [145]. The first suspicion of aromatic amine carcinogenesis was raised in 1895 when cases of bladder cancer in Swiss dye workers were reported [146]. Since then a number of epidemiologic investigations and animal studies have identified which aromatic amines are carcinogenic [147–149]. Because most aromatic amines have not been examined thoroughly for carcinogenic potential, researchers are attempting to develop theoretical models for determining which ones are carcinogenic [150–152]. Structural requirements, such as the type of aromatic ring system, the position of the amine group on the ring, and the presence and position of other substituents, are believed to be important to carcinogenic potential. Chemical carcinogens exert their effect by causing DNA damage, which leads to tumor formation. The metabolic reaction products, rather than the aromatic amines themselves, are believed to damage the DNA. These reaction products are electrophilic and are covalently bonded to the nucleic acid bases of DNA. The following reaction sequence has been proposed, where $ArNH_2$ is the aromatic amine [153].

$$ArNH_2 \xrightarrow{oxid.} ArNHOH \xrightarrow[pH<7]{} ArN\overset{+}{O}H_2 \rightarrow Ar\overset{+}{N}H \rightarrow$$

covalent bonding to nucleophilic sites on critical macromolecules

This reaction sequence implies that structural factors in the aromatic amine favoring the cation formation (e.g., electron-donating substituents ortho and para to the amino group) enhance carcinogenicity. Figure 4 is a sampling of some carcinogenic amines [154].

In addition to the effects cited in Table 1 [144], aromatic amines can cause a wide variety of other symptoms, such as eye and skin irritation. By drawing correlations from animal studies, exposure to some of these compounds may lead to liver and kidney damage.

5.2. Exposure Limits

Various countries have established their own exposure limits for workers [156–160]. As an illustration, Table 2 lists those aromatic amines

Table 1. Effects of the chronic administration of primary amines on the blood, liver, and bladder of dogs

	Methemoglobin formation	Toxicity and/or carcinogenesis (liver)	Bladder carcinogenesis
4-Aminobiphenyl [*92-67-1*]	+++	-	+++
2-Naphthylamine [*91-59-8*]	+	-	++
1-Naphthylamine [*134-32-7*]	-	-	-
Benzidine [*92-87-5*]	-	-	+
Aniline [*62-53-3*]	++	-	-
Dichlorobenzidine [*91-94-1*]	-	+	++
Methylenedianiline [*101-77-9*]	-	+++	+- b ∗
4,4′-Methylene-bis(2-chloroaniline) [*101-14-4*]	-	+	++
4,4′-Methylene-bis(2-methylaniline) [*838-88-0*]	-	+++	-
Bis aniline A [*2479-47-2*]	-	+-	+
4-Aminobiphenylamine [*101-54-2*]	-	++	+- b ∗

∗ Indicates only preneoplastic changes, no tumors.

Table 2. ACGIH aromatic amines workplace exposure limit (mg/m^3) [161]

Substance	TWA[a]	STEL[b]	MAK[c]
4-Aminobiphenyl (skin) [*92-67-1*]	A/b [d]	A/b [d]	III A 1 [f]
Aniline & homologues (skin) [*62-53-3*]	10	20	A 2 [e]

p-Phenylenediamine [*106-50-3*]	0.1 (skin)	-	0.1
o-Tolidine [*119-93-7*]	A 2 [e]	-	A 2 [e]
o-Toluidine (skin) [*95-53-4*]	9, A 2 [e]	-	-
Triphenylamine [*603-34-9*]	5	-	-
m-Xylene-α,α'-diamine [*1477-55-0*]	C [h] 0.1	-	-
Xylidene (all isomers except 2,4-xylidene) [*1300-73-8*]	10 (skin)	-	25

[a] Time-weighted average (8-h workday and a 40-h week);
[b] Short-term exposure limit (15-min TWA exposure);
[c] Maximum concentration values in the workplace;
[d] A recognized carcinogen. No assigned TLV. No exposure permitted by any route;
[e] A suspect carcinogen for man. Exposures should be controlled carefully;
[f] Compounds capable of inducing malignant tumors as shown by experience with humans;
[g] Unmistakably carcinogenic in animal experimentation only;
[h] Ceiling limit; TLV should not be exceeded even instantaneously, avoid skin contact, exposures are likely by skin absorption.

with exposure limits established in the United States (ACGIH) [161] and the Federal Republic of Germany (MAK) [162]. These recommendations are in addition to the U.S. Occupational Safety and Health Administration's Subpart Z exposure limits [163].

5.3. Protective Measures

Exposure to aromatic amines occurs primarily through two routes: skin contact and inhalation. Because of the potential health hazards, strict control measures are necessary to prevent exposure. From an industrial hygiene standpoint,

exposure is best prevented through the use of engineering controls. Whenever possible, processes containing aromatic amines should be enclosed. In a closed process exposure can occur only when equipment fails or when process streams are sampled. If a process is not enclosed, ventilation (both general diluted and local exhaust) should be used to prevent or reduce exposure. Ventilation specifications for a number of industrial processes are available [164]. When ventilation controls are not sufficient to lower exposure, respirators should be used until effective controls are installed. When respirators are used, a complete respiratory protection program should be instituted that includes regular training, maintenance, inspection, cleaning, and evaluation. Where skin contact may occur, workers should wear impervious clothing, including gloves and boots. Contaminated clothing should be stored in closed containers until discarded or cleaned. Safety showers should be available in the immediate area where exposure can occur so that the body can be washed quickly.

5.4. Environmental Monitoring

Routine monitoring of the airborne aromatic amine concentration should be performed to evaluate worker exposure. Measurements should be taken on a single 8-h sample or two 4-h samples to determine the 8-h TWA exposure. In addition, short-term samples should be taken to determine peak exposure when workers are doing specific tasks with a potential for exposure. Air samples should be taken in the worker's breathing zone. Several methods are available for airborne aromatic amine monitoring [165, 166] [167].

1. Introduction and History

The proteins, although they occur in an almost infinite variety, are composed of a relatively small number of basic building blocks, all α-amino acids. In addition, the amino acids fulfill certain regulatory functions in the metabolism and are required for the biosynthesis of other functional structures. This review is limited, for the most part, to the protein-forming amino acids, because they are by far the most widely distributed in nature and are of considerable economic interest.

The ca. 20 different α-amino acids found in proteins are simple organic compounds, in which an amino group and a side chain (R) are attached alpha to the carboxyl function. The R group may be aliphatic, aromatic, or heterocyclic and may possess further functionality.

At present over 200 naturally occurring α-amino acids are known [1–7]. Table 1 shows the α-amino acids found in proteins, where they occur exclusively as the L-enantiomers. D-Amino acids have been found only in the cell walls of some bacteria, in peptide antibiotics, and in the cell pools of some plants [10, 14, 15]. The L-amino acids are commonly abbreviated with three-letter or one-letter codes, as shown in Table 1 [4]. In addition, the abbreviation Glx or Z is used to refer to either glutamic acid or glutamine, and the abbreviation Asx or B is used to refer to either aspartic acid or asparagine. More recently

History. The history of amino acid chemistry began in 1806, when two French investigators, Vauquelin and Robiquet, isolated asparagine from asparagus juice. It was not until 1925 that Schryver and Burton isolated threonine from oat protein, the last of the ca. 20 protein-forming amino acids to be discovered. Strecker synthesized alanine in 1850 from acetaldehyde, ammonia, and hydrogen cyanide. Escher established the hypothesis of essential amino acids. Emil Fischer discovered that the amino acids were building blocks of the proteins. Abderhalden synthesized threonine from acrylic acid derivatives and methanol. Rose et al. recognized threonine as the last of the eight essential amino acids. D,L-Methionine was produced industrially in Germany in 1948, and in 1956 L-glutamic acid was produced by fermentation in Japan.

Origin of Amino Acids. The first amino acids were probably produced on the earth more than 3×10^9 years ago via "prebiotic synthesis" in the primordial atmosphere. The concept of prebiotic synthesis is based on laboratory experiments in which glycine, alanine, aspartic acid, glutamic acid, and other compounds were produced by the action of an electrical discharge on a simulated primordial atmosphere consisting of methane, hydrogen, water, and ammonia [16]. Since then, traces of amino acids have been detected in moon rocks, meteorites, and interstellar space.

2. Properties

2.1. Physical Properties and Structure

α-Amino acids are nonvolatile, white, crystalline compounds with no defined melting points. They are relatively stable on heating, generally decomposing at 250–300 °C. Both the low volatility and the thermal stability result from the low-energy dipolar structure (zwitterion, inner salt, betaine), which the amino acids assume in the solid state.

Evidence for this structure is provided by infrared and Raman spectra in which the bands typical of -NH_2 and -COOH moieties are absent. Equilibrium in solution also lies almost exclusively on the side of the dipolar form; therefore, amino acids are insoluble in nonpolar solvents and usually not very soluble in polar ones. The only amino acids that exhibit any appreciable solubility in alcohol are proline and hydroxyproline. Solubility in water depends on the pH: the minimum is at the isoelectric point.

This solubility minimum at the isoelectric point is quite useful for purifying and recrystallizing amino acids. The analytical technique for separating amino acid mixtures by electrophoresis is based on the fact that a specific amino acid does not migrate in an electric field at its isoelectric point, p*I*, a physical constant for each amino acid.

The structures and physical properties of the most important α-amino acids are given in Section 2.3.1.

Stereochemistry. With the exception of glycine, the simplest amino acid (R = H), all natural α-amino acids are chiral compounds occurring in two enantiomeric (mirror-image) forms.

Table 1. Common amino acids of proteins

Trivial name	IUPAC abbreviation	One-Letter Code	Protein	Content, g/100 g	
				[8]	[10]

L-Amino acid

D-Amino acid

The prefixes L and D express the absolute configuration at the α-carbon atom by means of the formal stereochemical relationship to L- or D-glyceraldehyde, the reference substance introduced by Emil Fischer in 1891. In addition to the spacial representations shown above, the Fischer projections are also universally recognized and used:

L-Amino acid

D-Amino acid

Polarimetric determination of the specific rotation $[\alpha]^t_D$ can be used to differentiate between the two enantiomers and to check their optical purity. The molecular rotation $[M]^t_D$ is less common:

$$[M]^t_D = \frac{M_r}{100} \cdot [\alpha]^t_D$$

M_r molecular mass; t temperature; D 589.3 nm (wavelength of the sodium D line). Other methods for investigating the structure of amino acid enantiomers include the Cotton effect (change in molecular rotation as a function of the wavelength of plane-polarized light), as reflected in optical rotational dispersion (reversal of the direction of the molecular rotation at the wavelength of the absorption maximum), and circular dichroism (differing absorption for left- and right-handed circularly polarized light). L-Amino acids exhibit a positive carbonyl Cotton effect, D-amino acids a negative one.

Isoleucine, threonine, and hydroxyproline each contain two chiral carbon atoms; therefore, they appear in four stereoisomeric forms. Cystine, which likewise contains two chiral carbons, has only three stereoisomers: L-, D-, and *meso*-cystine, the meso form having a plane of symmetry. According to the Cahn–Ingold–Prelog rule (R, S rule) [17], all proteinogenic L-α-amino acids, with the exception of L-cysteine and L-cystine, are S; the D-α-amino acids are R. According to this system, L-threonine, for example, is termed (2S, 3R)-threonine. However, the L- and D-descriptors are still in widespread use for the simple L-α-amino acids.

Absorption Spectra. Aliphatic amino acids exhibit no absorption in the UV region above 220 nm, with the exception of cystine (240 nm). The aromatic amino acids, phenylalanine, tyrosine, and tryptophan, absorb between 250 and 300 nm [1, vol. 2]. The exact position of the maximum and the molar extinction coefficient ϵ are affected by the pH of the aqueous solution.

Two infrared bands are especially characteristic of amino acids: 1560–1600 cm^{-1} ($-COO^-$) and ca. 3070 cm^{-1} $\left(-NH_3^+\right)$. These bands are also evidence of the bipolar nature of the amino acids.

2.2. Chemical Properties

Acidity and Basicity. The chemical properties of the α-amino acids are primarily the properties of the amino and carboxyl groups. Amino acids react with strong acids as proton acceptors (bases) and with strong bases as proton donors (acids). In acidic medium they are present predominantly as cations; in basic medium they are present predominantly as anions. Figure 1 shows the titration curves of glycine, glutamic acid, and lysine. The pK_1 and pK_2 values correspond to the inflection points of the titration curve, the pH value where the concentrations of the zwitterion form and the cationic or anionic form are equal. The pK_1, pK_2, and pI values can be calculated from the titration curves with the Henderson–Hasselbalch equation:

$$pK_1 = pH - \log \frac{\left[R-CH(NH_3^+)-COO^-\right]}{\left[R-CH(NH_3^+)-COOH\right]}$$

$$pK_2 = pH - \log \frac{\left[R-CH(NH_2)-COO^-\right]}{\left[R-CH(NH_3^+)-COO^-\right]}$$

$$pI = \frac{pK_1 + pK_2}{2}$$

Amino acids with additional basic or acidic groups (arginine, lysine, glutamic acid, cysteine)

exhibit additional pK values. Amino acids act as buffers in the region of their pK values.

Figure 1. Titration curves of glycine, glutamic acid, and lysine [9]

The pK_1 values show the amino acids to be considerably stronger acids than acetic acid. However, because of intramolecular protonation of the amine moiety by the carboxyl group, aqueous solutions of amino acids are only weakly acidic. The pH values of aqueous monoaminomonocarboxylic acids lie between 5.5 and 6.0. Solutions of the acidic amino acids aspartic acid and glutamic acid have pH values of ca. 2. The weakly basic amino acid histidine has a pH of 7.5 in aqueous solution; the more strongly basic amino acids lysine and arginine have pH values of ca. 11–12. These differences in acidities and basicities are utilized in the separation of amino acid mixtures by ion-exchange chromatography and electrophoresis.

Reactions. Because of their bifunctional and sometimes trifunctional character, the α-amino acids are capable of taking part in a variety of chemical reactions. Comprehensive treatments of these may be found in monographs and reviews [1, 9–12, 18].

The introduction of groups protecting the amino, carboxyl, and side-chain functions is especially important for peptide synthesis [13]. Additionally, α-amino acids play a prominent role as intermediates in the synthesis of heterocycles [19]. The chiral α-amino acids and their derivatives are inexpensive and, for the most part, readily available synthons for numerous natural products and pharmaceuticals. In many cases optically active amino acids can also be used to induce chirality during the course of a synthetic process [20].

α-Amino acids form *chelate-like complexes* with heavy metal ions. The best known are the dark blue, easily crystallized copper chelates:

Bis(glycinato) copper(II) hydrate

This complex formation can be used to protect both the α-amino and the carboxyl group during synthesis of ϵ-N-acetyl derivatives or carbamates of lysine or other side-chain derivatives. In these copper or cobalt complexes the α-carbon atom is activated sufficiently to react with aldehydes. A well-known example is the alkaline condensation of the glycine–copper complex with acetaldehyde, resulting in threonine. Especially important is the reaction of α-amino acids with ninhydrin to form a blue-violet dye, the basis of a sensitive optical method for detecting amino acids (see Chap. 6).

Free amino acids react with *nitrous acid* to yield α-hydroxycarboxylic acids, with retention of configuration. Volumetric measurement of the nitrogen gas set free is the basis of Van Slyke's method for the quantitative analysis of amino acids. Reaction of amino acid esters with nitrous acid gives the acid-labile diazocarboxylic acid esters. Treatment of N-alkyl- or N-arylamino acids with nitrous acid yields the N-nitroso derivatives, which can be dehydrated to sydnones in the presence of acetic anhydride:

α-Amino acids have found use as *organocatalysts* for asymmetric organic reactions, for example asymmetric versions of the aldol or the Mannich reactions [21]. The amino acids most often employed are L- or D-proline, their derivatives, or short-chain peptides based on proline.

Oxidizing agents attack the amino group, converting the amino acid into an iminocarboxylic acid. These are unstable and either hydrolyze to α-oxocarboxylic acids or decompose, after decarboxylation, into ammonia and the aldehyde containing one carbon atom less. Diketones, triketones, *N*-bromosuccinimide, or silver oxide may serve as the oxidizing agent. The best known example is the reaction with ninhydrin. Oxidative deamination also can be carried out enzymatically with D- or L-amino acid oxidases. This also proceeds via the α-iminocarboxylic acids, which subsequently are hydrolyzed to α-oxo acids:

This enantioselective enzymatic oxidative deamination is the basis of analytical methods for the determination of amino acid enantiomers.

The *N-acylation* of α-amino acids with acyl chlorides or anhydrides under Schotten-Baumann conditions produces *N*-acyl-α-amino acids, which have numerous uses. For example, the *N*-acetyl derivatives of D,L-amino acids (e.g., alanine, valine, methionine, phenylalanine, tryptophan) are intermediates in the production of L-amino acids by enzymatic resolution using aminoacylases (see Section 3.1). Amino acids acylated with naturally occurring fatty acid residues are used industrially as biodegradable surfactants.

If free amino acids are heated above 200 °C, especially in the presence of soda lime or metal ions, they readily *decarboxylate* to form amines. The enzymatic decarboxylation of amino acids gives biogenic amines. Some of these amines are physiologically active neurotransmitters (histamine, tyramine, dopamine, serotonin).

The *esters* are usually prepared by direct esterification, e.g., reaction of the α-amino acid with anhydrous alcohol in the presence of anhydrous hydrogen chloride. The initial product is the hydrochloride of the ester, which is liberated by addition of base. On standing or warming, the free esters of α-amino acids can eliminate alcohol to form 2,5-diketopiperazines:

Amino acid esters are useful intermediates for peptide synthesis because the carboxyl function is protected. The esters may be converted to amino alcohols by treatment with a strong reducing agent, such as lithium aluminum hydride.

Several cyclic derivatives of the α-amino acids are of industrial importance. The *hydantoins* or imidazolidine-2,4-diones, which have been used as intermediates in the synthesis of α-amino acids, are most conveniently prepared by treatment of aldehyde cyanohydrins with ammonium carbonate or urea. They also may be obtained by reacting amino acids with cyanates or isocyanates, the reaction proceeding via the ureidocarboxylic acid (hydantoic acid derivative):

Hydantoin derivative

The thiohydantoins are obtained by the reaction with isothiocyanates.

Dehydration of *N*-acylamino acids with acetic anhydride or carbodiimide yields *1,3-oxazolin-5-ones* (azlactones):

Racemization occurs readily during the reaction. The azlactones are intermediates in the synthesis of amino acids.

The *N-carboxylic acid anhydrides* (Leuchs anhydrides, 1,3-oxazolidine-2,5-diones) are often used in peptide synthesis, especially to prepare poly-α-amino acids. These reactive amino acid derivatives are obtained by treating the amino acid with phosgene in the presence of tertiary amines

or by elimination of benzyl chloride from *N*-benzyloxycarbonylamino acid chlorides.

2.3. Important Amino Acids

2.3.1. Proteinogenic Amino Acids

L-Alanine [*56-41-7*], 2-aminopropionic acid, $C_3H_7NO_2$, M_r 89.09, *mp* 314 °C (decomp.), $[\alpha]_D^{25}$ + 14.47° (c = 10.03 in 6 M HCl), solubility 16.51 (25 °C) g/100 g H_2O, p*I* 6.01, dissociation constants: pK_1 2.34, pK_2 9.69.

L-Arginine [*74-79-3*], 2-amino-5-guanidinovaleric acid, 2-amino-5[(aminoiminomethyl)amino]pentanoic acid, $C_6H_{14}N_4O_2$, M_r 174.20, *mp* 244 °C (decomp.), $[\alpha]_D^{25}$ + 27.58° (c = 2 in 6 M HCl), solubility 14.87 (20 °C) g/100 g H_2O, p*I* 10.76, dissociation constants: pK_1 2.01, pK_2 9.04 (α-NH_2), pK_3 12.48 (guanidyl). Hydrochloride: [*1119-34-2*], $C_6H_{15}ClN_4O_2$, M_r 210.66, *mp* 220 °C (decomp.), $[\alpha]_D^{25}$ + 11.7° (c = 5 in H_2O), solubility 75.1 (20 °C) g/100 g H_2O.

L-Asparagine [*70-47-3*], 2-aminosuccinamic acid, 2,4-diamino-4-oxobutanoic acid, $C_4H_8N_2O_3$, M_r 132.13, *mp* 236 °C (decomp.), $[\alpha]_D^{20}$ + 32.6° (c = 1 in 0.1 M HCl), solubility 3.11 (28 °C) g/100 g H_2O, p*I* 5.41, dissociation constants: pK_1 2.02, pK_2 8.8.

L-Aspartic acid [*56-84-8*], aminosuccinic acid, 2-amino-1,3-butanedioic acid, $C_4H_7NO_4$, M_r 133.10, *mp* 270 °C (decomp., sealed tube), $[\alpha]_D^{25}$ + 25.4° (c = 2 in 5 M HCl), solubility 0.5 (25 °C) g/100 g H_2O, p*I* 2.98, dissociation constants: pK_1 2.1, pK_2 3.86 (β-COOH), pK_3 9.82.

L-Cysteine [*52-90-4*], 2-amino-3-mercaptopropionic acid, 3-mercaptoalanine, $C_3H_7NO_2S$, M_r 121.16, *mp* 240 °C (decomp.), $[\alpha]_D^{25}$ + 9.7° (c = 8 in 1 M HCl), solubility 28 (25 °C) g/100 mL solution, 16 (20 °C) g/100 g H_2O, p*I* 5.02, dissociation constants: pK_1 1.71, pK_2 8.27 (–SH), pK_3 10.78. Hydrochloride monohydrate: [*7048-04-6*], $C_3H_{10}ClNO_3S$, M_r 175.64, *mp* (anhydr.) 178 °C (decomp.), $[\alpha]_D^{25}$ + 6.53° (calculated as cysteine) (c = 2 in 5 M HCl), solubility >100 (20 °C) g/100 g H_2O.

L-Cystine [*56-89-3*], 2,2′-diamino-3, 3′-dithiobis(propionic acid), 3,3′-dithiobis(2-aminopropanoic acid), $C_6H_{12}N_2O_4S_2$, M_r 240.30, *mp* 260°C (decomp.), $[\alpha]_D^{25}$ −212° (c = 1 in 1 M HCl), solubility 0.011 (25 °C) g/100 g H_2O, p*I* 5.02, dissociation constants: pK_1 1.04, pK_2 2.05 (-COOH), pK_3 8.0 (–NH_2), pK_4 10.25 (–NH_2).

L-Glutamic acid [*56-86-0*], 2-aminoglutaric acid, 2-amino-1,4-pentanedioic acid, $C_5H_9NO_4$, M_r 147.13, *mp* 224–225 °C (decomp.), $[\alpha]_D^{25}$ +31.5° (c = 2 in 5 M HCl, 20 °C), solubility = 0.843 (25 °C) g/100 g H_2O, p*I* 3.08, dissociation constants: pK_1 2.1, pK_2 4.07, pK_3 9.47.

L-Glutamine [*56-85-9*], 2-amino-glutaramic acid, 2,5-diamino-5-oxopentanoic acid, $C_5H_{10}N_2O_3$, M_r 146.15, *mp* 185-6 °C (decomp.), $[\alpha]_D^{25}$ + 31.8° (*c* = 2 in 1 M HCl), solubility 3.6 (19 °C) g/100 g H_2O, p*I* 5.65, dissociation constants: pK_1 2.17, pK_2 9.13.

Glycine [*56-40-6*], aminoacetic acid, $C_2H_5NO_2$, M_r 75.07, *mp* 262, 292 °C (decomp.), solubility 24.99 (25 °C) g/100 g H_2O, p*I* 6.06, dissociation constants: pK_1 2.35, pK_2 9.13.

L-Histidine [*71-00-1*], α-amino-1*H*-imidazole-4-propionic acid, 1*H*-imidazole-4-alanine, $C_6H_9N_3O_2$, M_r 155.16, *mp* 277, 287 °C (decomp.), $[\alpha]_D^{25}$ + 13.0° (*c* = 1 in 6 M HCl), solubility 4.29 (25 °C) g/100 g H_2O, p*I* 7.64, dissociation constants: pK_1 1.77, pK_2 6.1 (imidazolyl), pK_3 9.18. Hydrochloride monohydrate: [*5934-29-2*], $C_6H_{12}ClN_3O_3$, M_r 209.63, *mp* 259 °C (decomp.), solubility 16.99 (20 °C) g/100 g H_2O.

L-Hydroxyproline [*51-35-4*], *trans*-4-hydroxy-2-pyrrolidinecarboxylic acid, $C_5H_9NO_3$, M_r 131.13, *mp* 274 °C (decomp.), $[\alpha]_D^{22}$ −75.2° (*c* = 2 in H_2O), solubility 36.11 (25 °C) g/100 g H_2O, p*I* 5.82, dissociation constants: pK_1 1.92, pK_2 9.73.

L-Isoleucine [*73-32-5*], 2-amino-3-methylvaleric acid, 2-amino-3-methylpentanoic acid, $C_6H_{13}NO_2$, M_r 131.18, *mp* 285-6 °C (decomp.), $[\alpha]_D^{25}$ + 40.6° (*c* = 2 in 6 M HCl), solubility 4.117 (25 °C) g/100 g H_2O, p*I* 6.02, dissociation constants: pK_1 2.36, pK_2 9.68.

L-Leucine [*61-90-5*], 2-amino-4-methylvaleric acid, 2-amino-4-methylpentanoic acid, 2-aminoisocaproic acid, $C_6H_{13}NO_2$, M_r 131.18, *mp* 293-5, 314-5 °C (decomp.), $[\alpha]_D^{25}$ −10.9° (*c* = 0.52 in H_2O), solubility 2.19 (25 °C) g/100 g H_2O, p*I* 5.98, dissociation constants: pK_1 2.36, pK_2 9.6.

L-Lysine [*56-87-1*], 2,6-diaminohexanoic acid, 2,6-diaminocaproic acid, $C_6H_{14}N_2O_2$, M_r 146.19, *mp* 225-5 °C (decomp.), $[\alpha]_D^{25}$ + 25.9° (*c* = 2 in 5 M HCl), solubility >100 (25 °C) g/100 g H_2O, p*I* 9.47, dissociation constants: pK_1 2.18, pK_2 8.95 (α-NH_2), pK_3 10.53. Hydrochloride: [*657-27-2*], $C_6H_{15}ClN_2O_2$, M_r 182.65, *mp* 253-6 °C (decomp.), solubility 72.5 (25 °C) g/100 mL solution.

L-Methionine [*63-68-3*], 2-amino-4-(methylthio)butyric acid, 2-amino-4-(methylthio)butanoic acid, $C_5H_{11}NO_2S$, M_r 149.21, *mp* 283 °C (decomp.), $[\alpha]_D^{28}$ + 23.4° (*c* = 5 in 3 M HCl), solubility 5.37 (20 °C) g/100 g H_2O, p*I* 5.74, dissociation constants: pK_1 2.28, pK_2 9.21.

L-Phenylalanine [*63-91-2*], 2-amino-3-phenylpropionic acid, α-aminobenzenepropanoic acid, $C_9H_{11}NO_2$, M_r 165.19, *mp* 283-4 °C (decomp.), $[\alpha]_D^{20}$ −35.1° (*c* = 2 in H_2O), solubility 2.965 (25°C) g/100 g H_2O, p*I* 5.48, dissociation constants: pK_1 1.83, pK_2 9.13.

L-Proline [*147-85-3*], 2-pyrrolidinecarboxylic acid, 2-carboxypyrrolidine, $C_5H_9NO_2$,

M_r 115.13, *mp* 220–222 °C (decomp.), $[\alpha]_D^{25}$ −85.0° ($c = 1$ in H_2O), solubility 162.3 (25 °C) g/100 g H_2O, p*I* 6.3, dissociation constants: pK_1 2.0, pK_2 10.6.

L-Serine [*56-45-1*], 2-amino-3-hydroxypropionic acid, 2-amino-3-hydroxypropanoic acid, $C_3H_7NO_3$, M_r 105.09, *mp* 228 °C (decomp.), $[\alpha]_D^{26}$ −6.8° ($c = 10$ in H_2O), solubility 35.97 (20 °C) g/100 g H_2O, p*I* 5.68, dissociation constants: pK_1 2.21, pK_2 9.15.

L-Threonine [*72-19-5*], 2-amino-3-hydroxybutyric acid, 2-amino-3-hydroxybutanoic acid, $C_4H_9NO_3$, M_r 119.12, *mp* 253 °C (decomp.), $[\alpha]_D^{26}$ −28.6° ($c = 2$ in H_2O), solubility 9.03 (20 °C) g/100 g H_2O, p*I* 6.16, dissociation constants: pK_1 2.71, pK_2 9.62.

L-Tryptophan [*73-22-3*], 2-amino-3-(3′-indolyl)propionic acid, α-amino-1*H*-indole-3-propanoic acid, $C_{11}H_{12}N_2O_2$, M_r 204.23, *mp* 290–292 °C, 281 °C (decomp.), $[\alpha]_D^{25}$ −32.15° ($c = 1$ in H_2O), solubility 1.14 (25 °C) g/100 g H_2O, p*I* 5.88, dissociation constants: pK_1 2.38, pK_2 9.39.

L-Tyrosine [*60-18-4*], 2-amino-3-(4-hydroxyphenyl)propionic acid, [3-(4-hydroxyphenyl)]alanine, 2-amino-3-(*p*-hydroxyphenyl)propionic acid, α-amino-4-hydroxybenzenepropanoic acid, $C_9H_{11}NO_3$, M_r 181.19, *mp* 342-4 (sealed tube), 297–298 °C (decomp.), $[\alpha]_D^{25}$ −7.27° ($c = 4$ in 6 M HCl), solubility 0.045 (25 °C) g/100 g H_2O, p*I* 5.63, dissociation constants: pK_1 2.2, pK_2 9.11, pK_3 10.07 (–OH).

L-Valine [*72-18-4*], 2-amino-3-methylbutyric acid, 2-aminoisovaleric acid, $C_5H_{11}NO_2$, M_r 117.15, *mp* 315 °C (decomp.), $[\alpha]_D^{20}$ +26.7° ($c = 3.4$ in 6 M HCl), solubility 8.85 (25 °C) g/100 g H_2O, p*I* 5.96, dissociation constants: pK_1 2.32, pK_2 9.62.

2.3.2. Other Important Amino Acids

β-Alanine [*107-95-9*], 3-aminopropionic acid, $C_3H_7NO_2$, M_r 89.09, dissociation constant: pK_1 3.6, occurrence: apple, constituent of pantothenic acid, carnosine, anserine.

D-Alanine [*338-69-2*], 2-aminopropionic acid, D-Ala, $C_3H_7NO_2$, M_r 89.09, application: LHRH-antagonists, e.g., Abarelix (antineoplastic) [22].

D,l-Alanine [*302-72-7*], 2-aminopropionic acid, $C_3H_7NO_2$, M_r 89.09, *mp* 295 °C (decomp.), solubility 16.72 (25 °C) g/100 g H_2O, p*I* 6.11, dissociation constants: pK_1 2.35, pK_2 9.87.

α-Aminoisobutyric acid [*62-57-7*], 2-amino-2-methylpropionic acid, Aib, $C_4H_9NO_2$, M_r 103.12, application: growth hormone secretagogues, e.g., MK-0677 [23].

L-α-Aminobutyric acid [*1492-24-6*], 2-aminobutyric acid, L-Abu, $C_4H_9NO_2$, M_r 103.12, application: Levetiracetam (anticonvulsant) [24].

γ-Aminobutyric acid (GABA) [*56-12-2*], 4-aminobutyric acid, $C_4H_9NO_2$, M_r 103.12, occurrence: citrus fruits, sugar beet, brain.

D,L-Aspartic acid [*617-45-8*], aminosuccinic acid, 2-amino-1,3-butanedioic acid, $C_4H_7NO_4$, M_r 133.10, *mp* 275 °C (decomp., sealed tube), solubility 0.775 (25 °C) g/100 g H_2O, p*I* 2.98, dissociation constants: pK_1 2.1, pK_2 3.86 (β-COOH), pK_3 9.82.

L-Azetidine-2-carboxylic acid [*2133-34-8*], $C_4H_7NO_2$, M_r 101.10, application: Ximelagatran (thrombin inhibitor) [25].

Betaine [*107-43-7*], carboxymethyl-trimethyl ammonium betaine, $C_5H_{11}NO_2$, M_r 117.15, occurrence: sugar beet.

L-Carnitine [*541-15-1*], (3-carboxy-2-hydroxypropyl)trimethyl ammonium betaine, $C_7H_{15}NO_3$, M_r 161.2, occurrence: Lys metabolite, muscle.

L-Citrulline [*372-75-8*], 2-amino-5-ureidopentanoic acid, $C_6H_{13}N_3O_3$, M_r 175.19, *mp* 234–237 °C , 222 °C (decomp.), $[\alpha]_D^{25}$ + 24.2° (c = 2 in 5 M HCl), solubility 10.3 (20 °C) g/100 g H_2O, p*I* 5.92, dissociation constants: pK_1 2.43, pK_2 9.41; occurrence: urea cycle, watermelon.

D-Citrulline [*13594-51-9*], 2-amino-5-ureidopentanoic acid, D-Cit, $C_6H_{13}N_3O_3$, M_r 175.19, application: Cetrorelix (antineoplastic) [26].

Creatine [*57-00-1*], *N*-(aminoiminomethyl)-*N*-methylglycine, *N*-methylguanetic acid, $C_4H_9N_3O_2$, M_r 131.14, occurrence: muscle of vertebrates.

D-Cyclohexylalanine [*58717-02-5*], 2-amino-3-cyclohexylpropionic acid, D-Cha, $C_9H_{17}NO_2$, M_r 171.25, application: (thrombin inhibitors) [27].

(3*S*,4a*S*,8a*S*)-Decahydroisoquinolinecarboxylic acid [*115238-58-9*], decahydroisoquinoline-3-carboxylic acid, $C_{10}H_{17}NO_2$, M_r 183.26, application: Nelfinavir (antiviral) [28].

L-2,3-Diaminopropionic acid [*4033-39-0*], L-Dap, $C_3H_8N_2O_2$, M_r 104.11, application: Imidapril (antihypertensive) [29].

l-3,4-Dihydroxyphenylalanine (DOPA) [*59-92-7*], 2-amino-3-(3,4-dihydroxyphenyl)propionic acid, $C_9H_{11}NO_4$, M_r 197.17, occurrence: Tyr metabolite, faba bean.

D-Glutamic acid [*6893-26-1*], 2-aminoglutaric acid, 2-amino-1,4-pentanedioic acid, D-Glu, $C_5H_9NO_4$, M_r 147.12, application: Spiroglumide (CCK-B-antagonist) [30].

L-Homocysteine [*6027-13-0*], 2-amino-4-mercaptobutyric acid, $C_4H_9NO_2S$, M_r 135.18, occurrence: Met metabolite, mushrooms, application: Omapatrilat (ACE inhibitor) [31].

D-*p*-Hydroxyphenylglycine [*22818-40-2*], amino-(4-hydroxyphenyl)acetic acid, D-Phg(OH), $C_8H_9NO_3$, M_r 167.15, application: Amoxicillin (antibiotic) [32].

L-5-Hydroxytryptophan [*4350-09-8*], 2-amino-3-(5-hydroxy-1*H*-indol-3-yl)propionic acid, $C_{11}H_{12}N_2O_3$, M_r 220.22, occurrence: serotonin precursor.

D,L-Isoleucine [*443-79-8*], 2-amino-3-methylvaleric acid, 2-amino-3-methylpentanoic acid, $C_6H_{13}NO_2$, M_r 131.18, *mp* 292 °C (decomp.), solubility 2.011 (25 °C) g/100 g H_2O, p*I* 6.04, dissociation constants: pK_1 2.32, pK_2 9.76.

D,L-Leucine [*328-39-2*], 2-amino-4-methylvaleric acid, 2-amino-4-methylpentanoic acid, 2-aminoisocaproic acid, $C_6H_{13}NO_2$, M_r 131.18, *mp* 293-5, 332 °C (decomp.), solubility 1.00 (25 °C) g/100 g H_2O, p*I* 6.04, dissociation constants: pK_1 2.33, pK_2 9.74.

L-*tert*-Leucine [*20859-02-3*], 2-amino-3,3-dimethylbutyric acid, L-Tle, $C_6H_{13}NO_2$, M_r 131.18, application: div. pharmaceuticals [33].

D,L-Lysine hydrochloride [*70-53-1*], $C_6H_{15}ClN_2O_2$, M_r 182.65, *mp* 264 °C (decomp.), solubility 35.98 (20 °C) g/100 g H_2O.

D,L-Methionine [*59-51-8*], 2-amino-4-(methylthio)butyric acid, 2-amino-4-(methylthio)butanoic acid, $C_5H_{11}NO_2S$, M_r 149.21, *mp* 281 °C (decomp.), solubility 3.35 (25 °C) g/100 g H_2O, p*I* 5.74, dissociation constants: pK_1 2.28, pK_2 9.21.

***S*-Methyl-L-cysteine** [*1187-84-4*],2-amino-3-methylthiopropionic acid L-Cys(Me), $C_4H_9NO_2S$, M_r 135.18, application: Kynostatin-272 (antiviral) [34].

L-*S*-Methylmethionine (vitamin U) [*4727-40-6*], 3-amino-3-carboxy-propyl)-dimethyl sulfonium, $C_6H_{13}NO_2S$, M_r 163.24, occurrence: cabbage, asparagus.

D-3-(2′-Naphthyl)-alanine [*76985-09-6*], 2-amino-3-naphthalen-2-ylpropionic acid, D-Nal, $C_{13}H_{13}NO_2$, M_r 215.25, application: LHRH-antagonists, e.g., Abarelix (antineoplastic) [35].

D-Ornithine [*70-26-8*], 2,5-diaminovaleric acid, $C_5H_{12}N_2O_2$, M_r 132.16, *mp* 140 °C (decomp.), $[\alpha]_D^{25}$ + 16.5° (c = 4.6 in H_2O), solubility, p*I* 9.7, dissociation constants: pK_1 1.94, pK_2 8.65 (a-NH), pK_3 10.76; occurrence: urea cycle, shark liver, application: Atosiban (tocolytic) [36]. Hydrochloride: [*3184-13-2*], $C_5H_{13}ClN_2O_2$, M_r 168.6, *mp* 215 °C (decomp.), $[\alpha]_D^{25}$ + 28.3° (calculated as ornithine) (c = 2 in 5 M HCl), solubility 54.36 (20 °C) g/100 g H_2O.

D-Penicillamine [*52-67-5*], 2-amino-3-mercapto-3-methylbutyric acid, $C_5H_{11}NO_2S$, M_r 149.21, occurrence: hydrolysis product of penicillin.

D-Phenylalanine [*673-06-3*], 2-amino-3-phenylpropionic acid, α-aminobenzenepropanoic acid, D-Phe, $C_9H_{11}NO_2$, M_r 165.19, application: Nateglinide (antidiabetic) [38].

D,L-Phenylalanine [*150-30-1*], 2-amino-3-phenylpropionic acid, α-aminobenzenepropanoic acid, $C_9H_{11}NO_2$, M_r 165.19, *mp* 284–288 °C, 320 °C (decomp.), solubility 1.29 (25 °C) g/100 g H_2O, p*I* 5.91, dissociation constants: pK_1 2.58, pK_2 9.24

D-*p*-Cl-Phenylalanine [*14091-08-8*], 2-amino-3-(4-chlorophenyl)propionic acid, D-Phe(Cl), $C_9ClH_{10}NO_2$, M_r 199.63, application: LHRH antagonists, e.g., Abarelix (antineoplastic) [39].

L-*p*-NO_2-Phenylalanine [*949-99-5*], 2-amino-3-(4-nitrophenyl)propionic acid, L-Phe(NO_2), $C_9H_{10}N_2O_4$, M_r 210.17, application: Zolmitriptan (antimigraine) [40].

***S*-Phenyl-L-cysteine** [*34317-61-8*], 2-amino-3-phenylthiopropionic acid, L-Cys(Ph), $C_9H_{11}NO_2S$, M_r 197.61, application: Nelfinavir (antiviral) [41].

D-Phenylglycine [*875-74-1*], 2-amino-phenyl-acetic acid, D-Phg, $C_8H_9NO_2$, M_r 151.16, application: Ampicillin (antibiotic) [42].

L-Pipecolic acid [*3105-95-1*], piperidine-2-carboxylic acid, L-Pec, $C_6H_{11}NO_2$, M_r 129.16, occurrence: legumes, metabolite of Lys, application: Ropivacaine (local anesthetic) [43].

L-Piperazinecarboxylic acid [*147650-70-2*], piperazine-2-carboxylic acid, $C_5H_{10}N_2O_2$, M_r 130.15, application: Indinavir (antiviral) [44].

D-Piperidine-3-carboxylic acid [*25137-00-2*], nipecotic acid, $C_6H_{11}NO_2$, M_r 129.7, application: Tiagabine (anticonvulsant) [45].

D,l-Proline [*609-36-9*], 2-pyrrolidinecarboxylic acid, 2-carboxypyrrolidine, $C_5H_9NO_2$, M_r 115.13, *mp* 205 °C (decomp.), p*I* 6.3, dissociation constants: pK_1 2.0, pK_2 10.6.

D-Proline [*344-25-2*], 2-pyrrolidinecarboxylic acid, 2-carboxypyrrolidine, D-Pro, $C_5H_9NO_2$, M_r 115.13, application: Eletriptan (antimigraine) [46].

D-3-(3′-Pyridyl)-alanine [*70702-47-5*], 2-amino-3-pyridin-3-ylpropionic acid, D-Pal, $C_8H_{10}N_2O_2$, M_r 166.18, application: LHRH antagonist, e.g. Abarelix (antineoplastic) [47].

L-Pyrrolysine [*448235-52-7*], N^6-[(3*R*)-1,5-didehydro-3-methyl-D-prolyl]- L-lysine, $C_{12}H_{21}N_3O_3$, M_r 255.31, the 22nd natural amino acid to be discovered, occurrence: archaea as part of methane-producing enzymes [37].

L-Saccharopine [*997-68-2*], 2-(5′-amino-5′-carboxypentylamino)pentanedioic acid, $C_{11}H_{20}N_2O_6$, M_r 276.27, occurrence: baker′s and brewer′s yeast.

L-Selenocysteine [*10236-58-5*], 3-selenyl-L-alanine, Sec, U, $C_3H_7NO_2Se$, M_r 168.05, the 21st natural amino acid to be discovered [48]. Often found in the form of its dimer, *R*,*R*-selenocystine [*29621-88-3*], $C_6H_{12}N_2O_4Se_2$, M_r 334.09.

L-Selenomethionine [*3211-76-5*], (*S*)-2-amino-4-(methylseleno)butanoic acid, (*S*)-2-amino-4-(methylseleno)butanoic acid, $C_5H_{11}NO_2Se$, M_r 196.11, occurrence: plant tissue, application: dietary supplement [49].

D,l-Serine [*302-84-1*], 2-amino-3-hydroxypropionic acid, 2-amino-3-hydroxypropanoic acid, $C_3H_7NO_3$, M_r 105.09, *mp* 246 °C (decomp., sealed tube), solubility 5.023 (25 °C) g/100 g H_2O, p*I* 5.68, dissociation constants: pK_1 2.21, pK_2 9.15.

D-Serine [*312-84-5*], 2-amino-3-hydroxypropionic acid, 2-amino-3-hydroxypropanoic acid, D-Ser, $C_3H_7NO_3$, M_r 105.09, application: D-cycloserine (cognition enhancer) [50].

L-Thiazolidine-4-carboxylic acid [*34292-47-7*], L-Tia, $C_4H_7NO_2S$, M_r 133.16, application: Kynostatin-272 (antiviral) [34].

D,L-Threonine [*80-68-2*], 2-amino-3-hydroxybutyric acid, 2-amino-3-hydroxybutanoic acid, $C_4H_9NO_3$, M_r 119.12, *mp* 234-5 °C (decomp.), solubility 20.5 (25 °C) g/100 g H_2O, p*I* 6.16, dissociation constants: pK_1 2.71, pK_2 9.62.

L-Thyroxine [*51-48-9*], 2-amino-3-[4-(4-hydroxy-3,5-diiodophenoxy)-3,5-diiodophenyl]propionic acid, $C_{15}H_{11}NO_4$, M_r 269.18, occurrence: thyroid gland.

D,L-Tryptophan [*54-12-6*], 2-amino-3-(3′-indolyl)propionic acid, α-amino-1*H*-indole-3-propanoic acid, $C_{11}H_{12}N_2O_2$, M_r 204.23, *mp* 285 °C (decomp.), solubility 0.25 (30 °C) g/100 g H_2O, p*I* 5.88, dissociation constants: pK_1 2.38, pK_2 9.39.

D,L-Tyrosine [*556-03-6*], 2-amino-3-(4-hydroxyphenyl)propionic acid, [3-(4-hydroxyphenyl)]alanine, 2-amino-3-(*p*-hydroxyphenyl)propionic acid, α-amino-4-hydroxybenzenepropanoic acid, $C_9H_{11}NO_3$, M_r 181.19, *mp* 340 °C, 318 °C (decomp.), solubility 0.351 (25 °C) g/100 g H_2O, p*I* 5.63, dissociation constants: pK_1 2.2, pK_2 9.11, pK_3 10.07 (–OH).

D,L-Valine [*516-06-3*], 2-amino-3-methylbutyric acid, 2-aminoisovaleric acid, $C_5H_{11}NO_2$, M_r 117.15, *mp* 298 °C (decomp., sealed tube), solubility 7.09 (25 °C) g/100 g H_2O, p*I* 6.0, dissociation constants: pK_1 2.29, pK_2 9.72.

D-Valine [*640-68-6*], 2-amino-3-methylbutyric acid, D-Val, $C_5H_{10}NO_2$, M_r 116.14, application: Fluvalinate (insecticide) [51].

3. Industrial Production of Amino Acids

Amino acids can be classified as natural, including the proteinogenic (occurring in proteins) amino acids, or as nonnatural. Originally, only

Figure 2. Routes for production of amino acids

20 amino acids were believed to be genetically coded, but the recent discoveries of selenocysteine and pyrrolysine have demonstrated that additional amino acids could be coded by subverting a stop codon. The following sections will focus on production methods for the principal proteinogenic amino acids, which are of major importance in nutrition and as feed additives.

3.1. General Methods

Four basic processes (see Fig. 2) are suitable for the production of amino acids: chemical synthesis (including asymmetric synthesis), extraction, fermentation, and enzymatic routes. The *classical chemical synthesis* is applied to produce either the achiral amino acid glycine or racemic amino acids, for instance D,L-methionine. If L-amino acids are to be manufactured by this route, the chemical synthesis has to be followed by a resolution step. In some cases L-amino acids are directly produced from prochiral precursors by means of enzymes as chiral catalysts. For L-cysteine, transformation of another amino acid (cystine) is an important method. Catalytic asymmetric syntheses have been developed for many L-amino acids and their D-antipodes, but few have been applied on an industrial scale. The *extraction process* has the advantage of offering access to nearly all the proteinogenic L-amino acids by isolation from protein hydrolysates. The starting materials are protein-rich products, such as keratin, feathers, blood meal, or technical gelatin (see Fig. 3). This process is now generally being replaced by other methods, because of customer preference for materials not of animal origin. Some amino acids, such as L-tyrosine, can be economically isolated from plant residues, for example sugar beet molasses.

Figure 3. Extraction of amino acids

Table 2. Production of amino acids, methods, and production volume

Type	Amino acid	Preferred production method
I	L-Alanine	enzymatic catalysis, fermentation
I	L-Asparagine	extraction, chemical synthesis
I	L-Glutamine	fermentation, extraction
I	L-Histidine	fermentation, extraction
I	L-Hydroxyproline	fermentation, extraction
I	L-Isoleucine	fermentation, extraction
I	L-Leucine	fermentation, extraction
I	L-Methionine	enzymatic resolution
I	L-Proline	fermentation, extraction
I	L-Serine	fermentation, extraction
I	L-Tyrosine	extraction
I	L-Valine	enzymatic catalysis, fermentation
II	L-Arginine	fermentation, extraction
II	L-Cysteine	fermentation, enzymatic catalysis (via reduction of L-cystine)
II	L-Tryptophan	fermentation
III	Glycine	chemical synthesis
III	L-Aspartic acid	enzymatic catalysis
III	L-Phenylalanine	fermentation
III	L-Threonine	fermentation
IV	D,L-Methionine	chemical synthesis and enzymatic resolution
IV	L-Glutamic acid	fermentation
IV	L-Lysine	fermentation
Type I	100–1000	t/a
Type II	1000–8000	t/a
Type III	8000–100 000	t/a
Type IV	100 000–800 000	t/a

The use of overproducing microbial strains (→ Biotechnology; → Enzymes, Chap. 6.5) in *fermentation processes* with sucrose or glucose as carbon source is currently the most economic production method for bulk amino acids such as monosodium L-glutamate, L-lysine hydrochloride, and L-threonine. In the last ten years, this has become the method of choice for production of other amino acids, such as L-phenylalanine, L-tryptophan, and L-cysteine. Classical breeding and mutagenesis as well as recombinant DNA techniques are generally employed to modify the biosynthetic pathway and force the bacteria to overproduce the corresponding metabolites. Industrially used mutants are usually characterized by genetic markers introduced by methods of deregulation, e.g., auxotrophic mutants, in order to release key enzymes from strict regulation by metabolites (feedback inhibition and repression). A different way to obtain overproducing strains consists of screening of regulatory mutants, in that important enzymes are resistant to toxic compounds, i.e., analogues or derivatives of amino acids. In such cases high amino acid concentrations do not inhibit the enzymatic key in the pathway of biosynthesis and thus result in high production rates of the desired amino acid. The fourth method, *enzymatic catalysis*, uses whole cells or active cell components (enzymes) as such or, if possible, as immobilized biocatalysts in continuously operated reactors. The competitiveness of enzymatic processes depends on the availability and price of substrate, the activity and stability of the involved enzyme(s) and on the simplicity of product recovery. For some general reviews on amino acid synthesis, emphasizing the chemical and biocatalytic methods, see [52–56].

In Table 2 the amino acids and their preferred production methods are listed, classified by the size of production volume. Table 3 specifies the amino acids produced by direct fermentation of carbohydrates.

3.2. Production of Specific Amino Acids

3.2.1. L-Alanine

L-Alanine is industrially produced from L-aspartic acid by means of immobilized *Pseudomonas dacunhae* cells in a pressurized bioreactor [69]. In direct fermentation microorganisms usually accumulate D,L-alanine because of alanine racemase also present. With a D-cycloserine resistant mutant selected from *Brevibacterium lactofermentum*, it is possible to obtain 46 g/L D-alanine with an enantiomeric excess (e.e.) of 95 % [58]. An alanine racemase-deficient mutant of *Arthrobacter oxydans* was reported, that produces 75 g/L L-alanine from glucose with a yield of 52 % and 95 % e.e. [57]. A small amount of L-alanine is still isolated from protein hydrolysates.

3.2.2. l-Arginine

L-Arginine is today produced mainly by fermentation. Suitable strains for fermentation are deregulated mutants derived from *Corynebacterium glutamicum* and *Bacillus subtilis* accumulating 25–35 g/L L-arginine from glucose [70]. Very potent strains of *Serratia marcescens*

Table 3. Amino acids produced by direct fermentation from carbohydrates

Amino acid	Type of mutant	Amino acid yield, g/L	Reference
L-Alanine (95 % e.e.)	*Athrobacter oxydans*	75	Hashimoto and Katsumata (1994) [57]
D-Alanine (95 % e.e.)	*Brevibacterium lactofermentum*	46	Yahata et al. (1993) [58]
L-Arginine	*Serratia marcescens* AU^r-1	100	Chibata et al. (1983) [59]
L-Glutamine	*Brevibacterium flavum* AJ 3409	57	Yoshihara et al. (1992) [60]
L-Histidine	*Serratia marcescens*	40	Sugiura et al. (1987) [61]
L-Isoleucine	*Escherichia coli* H-8461	30	Kino et al. (1993) [62]
L-Leucine	*Brevibacterium flavum* AJ 3686	19.5	Yoshihara et al. (1992) [63]
L-Lysine	*Corynebacterium glutamicum*	>120	Oh et al. (1990) [64]
L-Methionine	*Pseudomonas putida* VKPM V-4167	3.5	University Odessa (1992) [65]
L-Phenylalanine	*Escherichia coli* MWPWJ304/pMW16	51	Ikeda et al. (2003) [56]
L-Proline	*Brevibacterium flavum* AP113	97.5	Kocarian et al. (1986) [66]
L-Serine	*Methylobacterium* sp. MN43	65	Ikeda et al. (2003) [56]
L-Threonine	*Escherichia coli* BKIIM B-3996	85	Debabov et al. (1990) [67]
L-Tryptophan	*Corynebacterium glutamicum* KY9218/pKW9901	50	Ikeda et al. (1994) [68]
L-Valine	*Corynebacterium glutamicum VR 3*	99	Ikeda et al. (2003) [56]

derived from mutants obtained by transduction, having feedback-insensitive and derepressive enzymes of arginine biosynthesis and 6-azauracil resistance, are able to produce 60–100 g/L L-arginine [59]. A small amount of L-arginine is isolated from protein hydrolysates.

3.2.3. l-Aspartic Acid and Asparagine

L-Aspartic acid is industrially manufactured by an enzymatic process in which aspartase (L-aspartate ammonia lyase, EC 4.3.1.1) catalyzes the addition of ammonia to fumaric acid [71]. Advantages of the enzymatic production method are higher product concentration and productivity and the formation of fewer byproducts. Thus L-aspartic acid can be easily separated from the reaction mixture by crystallization.

A process involving continuous production of L-aspartic acid by means of carrier-fixed aspartase isolated from *Escherichia coli* was first commercialized in Japan [72]. An economically attractive process for L-aspartic acid uses resting or dried cells with a high aspartase content, e.g., a 4.5 % suspension of aspartase-containing *Brevibacterium flavum* cells could be recycled in seven repeated batches and concentrations up to 166 g/L L-aspartate could be achieved [73]. In 1973, an immobilized cell system based on *E. coli* cells entrapped in polyacrylamide gel lattice was introduced for large-scale production [74]. This example represents the first industrial application of immobilized microbial cells in a fixed-bed reactor. Further improvements, immobilization of the cells in κ-carrageenan, provided remarkably increased operational stability, resulting in biocatalyst half-lives of almost two years [75]. A column packed with the κ-carrageenan-immobilized system allows a theoretical productivity of 140 $g\,L^{-1}\,h^{-1}$ L-aspartate.

As L-aspartic acid gained importance as intermediate for the manufacture of the dipeptide sweetener aspartame (methyl ester of L-aspartyl-L-phenylalanine) improved processes were developed. For continuous production of L-aspartic acid *Escherichia coli* strains immobilized with polyurethane [76] or with polyethylenimine and glass fiber support [77] and κ-carrageenan-immobilized *Pseudomonas putida* [78] have been reported and protected, respectively. Less successful was the search for strains that are overproducing L-aspartate by fermentation of sugar. A pyruvate kinase-deficient mutant of *Brevibacterium flavum* accumulates up to 22.6 g/L L-aspartic acid in glucose-containing medium [79], not enough to be competitive with the enzymatic processes. On the other hand, genetic recombination techniques have helped to improve aspartase-containing strains. An *asp*A gene bearing plasmid (pBR322:*asp*A-*par*) was able to elevate aspartase formation in *Escherichia coli* K 12 about 30-fold [80].

L-Asparagine can be isolated as a byproduct from the production of potato starch. A simple synthesis of L-asparagine starts from L-aspartic acid which is esterified to the β-methyl ester followed by treatment with ammonia [81].

3.2.4. L-Cystine and L-Cysteine

L-Cysteine used to be produced almost exclusively by hydrolysis of hair or other keratins. The amino acid isolated was L-cystine, which was reduced electrolytically to L-cysteine. L-Cysteine has also been prepared from β-chloro-D,L-alanine and sodium sulfide with cysteine desulfhydrase, an enzyme obtained from, e.g., *Citrobacterium freundii* [82].

Today, however, the main processes for cysteine production are biological. A direct fermentation process has been developed for the manufacture of L-cystine, using a modified E. coli bacterium [83]. The technology has been extended to prepare other modified L-cysteine analogues [84]. An enzymatic process for L-cysteine has been successfully developed using microorganisms capable to hydrolyze 2-amino-Δ^2-thiazoline 4-carboxylic acid (ATC) which is readily available from methyl α-chloroacrylate and thiourea. A mutant of *Pseudomonas thiazolinophilum* converts D,L-ATC to L-cysteine in 95 % molar yield at product concentrations higher than 30 g/L [85].

3.2.5. L-Glutamic Acid

In 1957, a soil bacterium was discovered [86] which was able to excrete considerable amounts of L-glutamate. Fermentation processes using strains of this bacterium, later called *Corynebacterium glutamicum*, have been successfully commercialized not only for L-glutamic acid but also for the production of other economically important amino acids [87, 88]. Numerous coryneform microorganisms have been isolated and found to be able to overproduce L-glutamic acid and other amino acids. Examples of these microorganisms are *Brevibacterium flavum*, *Brevibacterium lactofermentum*, and *Microbacterium ammoniaphilum*. Because of minor differences in the character of those bacteria [89] which are all gram-positive, nonspore-forming, nonmotile and all require biotin for growth, the name of genus *Corynebacterium* was suggested for these coryneform bacteria [90].

For industrial production of L-glutamic acid, molasses (sucrose), starch hydrolysates (glucose) and ammonium sulfate are generally used as carbon and nitrogen sources, respectively [91]. Key factors in controlling the fermentation are the presence of biotin in optimal concentration — to optimize cell growth and the excretion of L-glutamate — and sufficient supply of oxygen to reduce the accumulation of byproducts, such as lactic and succinic acid. In biotin-rich fermentation media the addition of penicillin or cephalosporin C favors the overproduction of L-glutamic acid due to effects on the cell membrane. The supplementation of fatty acids also results in an increased permeability of the cells thus enhancing glutamate excretion. In the past the mechanism of glutamate excretion was simply explained as a "leakage" or "overflow" phenomenon [92]. In the beginning of the 1990s it was reported that a specific carrier system exists [93, 94], which is responsible for active glutamate transport in *Corynebacterium glutamicum.* Generally the intracellular accumulation of glutamate does not reach levels sufficient for feedback control in glutamate overproducers due to rapid excretion of glutamate. However, the regulatory mechanisms of L-glutamic acid biosynthesis have been studied intensively to obtain mutants with increased productivity. Two enzymes have been shown to play key roles in the biosynthesis of L-glutamic acid [95].

1) Phosphoenolpyruvate carboxylase (PEPC) catalyzes carboxylation of phosphoenolpyruvate to yield oxaloacetate; it is inhibited by L-aspartic acid and repressed by both L-aspartic and L-glutamic acids.
2) α-Ketoglutarate dehydrogenase (KDH) converts α-ketoglutarate to succinyl-CoA. In L-glutamate overproducing strains KDH limits further oxidation of α-ketoglutarate to carbon dioxide and succinate, thus favoring formation of L-glutamic acid.

In L-glutamate overproducing strains the K_m value of KDH for α-ketoglutarate was nearly two magnitudes lower than that of L-glutamic acid dehydrogenase (GDH) which catalyzes the last step, the reductive amination of α-ketoglutarate to L-glutamate. Consequently, V_{max} of GDH was proven to be about 150 times higher than that of KDH. The *Corynebacterium glutamicum gdh* gene has been isolated and characterized [96]. A strain of *Microbacterium ammoniaphilum* cultured under biotin-deficient conditions produced 58 % of L-glutamic acid

formed from glucose via phosphoenolpyruvate, citrate, and of α-ketoglutarate and the other 42 % via the tricarboxylic acid (TCA) or the glyoxylate cycle [97]. In large-scale production the formation of trehalose very often reduces the product yield. Trehalose consists of two α-1,1 bound glucose molecules and is excreted by the bacteria as a material with protects the cell against high osmotic pressure (osmoprotectant). A process was recently developed and successfully industrialized in which trehalose formation is controlled and decreased by culturing the overproducing mutant in media containing invert sugar from molasses [98, 99].

Today wild type isolates as well as mutants developed by classical breeding or even strains constructed by modern techniques, using cell fusion or recombinant DNA methods [100], are available for industrial L-glutamate production. In addition a new type of fermentation process was reported which uses a strain that overproduces L-glutamic acid and L-lysine simultaneously. The cultivation of an auxotrophic regulatory mutant of *Brevibacterium lactofermentum* in a medium, supplemented with polyoxyethylenesorbitan monopalmitate as surface-active agent, resulted in the accumulation of 162 g L-amino acids per liter (105 g L-lysine · HCl + 57 g L-glutamic acid). This corresponds to a production rate of 3.8 g (L-lysine · HCl + L-glutamic acid) per liter per hour [101].

The success of an economic production basically depends on the experience in fermentation technology, in up- and downstream processing and on the skill of employees in research, development, and production. A multistep inoculation procedure followed by the fed-batch mode (→ Biotechnology, Chap. 6.2) in the main fermentation up to 500 m^3 scale is still the preferred technology for the production of L-glutamic acid.

Critical operations are the steam-forced sterilization of the fermenter and batchwise or continuous sterilization of the culture medium to prevent contamination by foreign microbes. During fermentation the temperature, pH, dissolved oxygen, and the sugar consumption have to be controlled as important process parameters. When the fermentation is completed after 40–60 h, the production strain may have accumulated more than 150 g/L L-glutamic acid. After deactivation of the broth, the recovery of the product is started by biomass separation using centrifuges or ultrafiltration units, concentration of the centrifugate or filtrate, followed by crystallization, filtration and drying. A scheme of production steps is given in Figure 4.

Figure 4. Flow diagram of fermentation and downstream processing of L-glutamic acid

3.2.6. L-Glutamine

Microbial L-glutamine producers were selected from wild type glutamate-producing coryneform bacteria. A sulfaguanidine resistant mutant of *Brevibacterium flavum* accumulates 41 g/L L-glutamine in 48 h from 10 % glucose [102]. A yield of 44 % was achieved by the mutant *Brevibacterium flavum* AJ3409 [60].

3.2.7. L-Histidine

Efficient L-histidine fermentation can be performed with strains of *Corynebacterium glutamicum* and *Serratia marcescens*. A mutant of *Corynebacterium glutamicum* having resistance to 8-azaguanine, 1,2,4-triazole-3-alanine, 6-mercaptoguanine, 6-methylpurine, 5-methyltryptophan and 2-thiouracil, produces 15 g/L of L-histidine. Only after introduction of these resistance markers by mutagenesis is the mutant capable of releasing this amount of L-histidine into the nutrient solution. A strain of *Serratia marcescens* having both characters, feedback-insensitive and derepressed histidine enzymes combined with transductional techniques and 6-methylpurine resistance, accumulates 23 g/L L-histidine [103]. By amplification of the genes *his*G, *his*D, *his*B, *his*C in *Serratia marcescens* the final concentration of L-histidine could be elevated from 28 g/L to 40 g/L [61].

L-Histidine can also be produced by isolation from blood-meal hydrolysates [104].

3.2.8. L-Hydroxyproline

L-Hydroxyproline (*trans*-4-hydroxy-L-proline, 2*S*,4*R*-hydroxyproline) is today mainly obtained by enzymatic hydroxylation of L-proline with genetically modified *E. coli* [105, 106]. The proline 4-hydroxylase specifically produces the 4-*trans* isomer. This method has almost completely replaced the isolation from hydrolysates of gelatin or other collagens. An unusual feature of this amino acid is that it is not incorporated into collagen during biosynthesis at the ribosome, but is formed from L-proline by a post-translational hydroxylation reaction.

3.2.9. L-Isoleucine

An advantageous fermentation method for production of L-isoleucine is the use of chemically synthesized substrates that only require a few steps to be converted to L-isoleucine. Among these the natural precursors 2-ketobutyrate [107] or D,L-2-hydroxybutyrate [108] have been used for the production with *Corynebacterium glutamicum*. A leucine requiring mutant of *Corynebacterium glutamicum*, with increased D-lactate utilization and consuming D,L-2-hydroxybutyrate, accumulates 13.4 g/L L-isoleucine. However, exploitation of this process is hampered by formation of by-products [109]. Sugar based L-isoleucine processes have been developed with strains of *Corynebacterium glutamicum* [110], *Serratia marcescens* [111], and *Escherichia coli* [112–114]. The mutant *Escherichia coli* H-8285, being resistant to thiaisoleucine, arginine hydroxamate, and D,L-ethionine accumulates 26 g/L L-isoleucine in 45 h in a fed-batch process [115]. Introduction of resistance to 6-dimethylaminopurine in strain H-8285 resulted in a mutant *Escherichia coli* H-8461 that increased L-isoleucine accumulation to 30.2 g/L [62]. The biosynthesis of L-isoleucine has been investigated in detail on the level of involved genes [63], thus recombinant strains are being constructed with high productivity and selectivity. An appropriate balance of homoserine dehydrogenase and threonine dehydratase activities in the construct *Corynebacterium glutamicum* DR17/pECM3::*ilv*A(V323A) with feedback-resistant aspartate kinase create a specific productivity of 0.052 g L-isoleucine per gram dry biomass per hour [116]. The recombinant strain *Escherichia coli* AJ13100 produces L-isoleucine from glucose with high selectivity in 30 % yield [117].

3.2.10. L-Leucine

L-Leucine can be manufactured by fermentation, precursor fermentation, or, less commonly today, by isolation from protein hydrolysates. Using a fed-batch culture of *Corynebacterium glutamicum* ATCC 13032 32 g/L 2-ketoisocaproate can be converted to 24 g/L L-leucine by the transaminase B reaction [118]. With the method of direct fermentation L-leucine can be produced by either α-aminobutyric acid-resistant mutants of *Serratia marcescens* or by 2-thiazole-alanine-resistant coryneform strains [119]. *Brevibacterium flavum* AJ3686 accumulates 19.5 g/L L-leucine (15 % yield) [120].

3.2.11. L-Lysine

The most potent microorganisms to overproduce L-lysine are mutants derived from *Corynebacterium glutamicum,* a gram-positive bacterium first introduced as an L-glutamate producing microbe; the wild strains themselves are not able to excrete L-lysine. Mainly auxotrophic and regulatory mutants of this bacterium have been developed by classical breeding methods and mutagenesis. The following techniques have been applied to channel the metabolic pathway in the biosynthesis of amino acids:

Screening for auxotrophic mutants, in order to release key enzymes, for instance aspartate kinase, from strict regulation by metabolites (feedback inhibition).

Screening for regulatory mutants, in which aspartate kinase is resistant to toxic analogues of L-lysine, such as *S*-(2-aminoethyl)-L-cysteine (AEC) or *O*-(2-aminoethyl)-L-serine. In such strains high lysine concentrations do not inhibit the enzymatic key step, the formation of 4-aspartylphosphate from L-aspartase catalyzed by aspartate kinase.

Screening for mutants having amino acid auxotrophy combined with deregulation.

Screening for regulatory mutants having additional enzyme defects (reduced pyruvate kinase) and low levels of other enzymes (citrate synthase).

As a modern technique, cell fusion with the method of protoplast fusion has been successively applied for breeding of industrial microorganisms [121, 122]. This technique allows the combination of positive characteristics of different strains such as high selectivity and high productivity. In fermentation with media of inhibitory osmotic stress (i.e., high substrate concentration results in high osmotic pressure on the cell that inhibits the performance of the mutant) the sugar consumption rate and L-lysine production rate of some mutants can be stimulated by the addition of glycine [123]. Another attractive approach is the development of thermophilic strains. A mutant of *Corynebacterium thermoaminogenes* was patented which is capable of growing at a temperature $> 40\,^{\circ}C$ and accumulating L-lysine in the culture medium [124].

Meanwhile, regulation of lysine excretion in overproducing strains is known in detail [125, 126]. Thus more attention should be paid to process development in the fields of molecular biology, biochemistry, and physiology and to finding new approaches for developing improved overproducing mutants [127]. The most specific and well-directed methods for strain development are offered by recombinant DNA techniques.

In principle all genes encoding the relevant enzymes in L-lysine biosynthesis have been isolated, characterized, and amplified in coryneform bacteria to enhance L-lysine formation [128]. As an example, amplification of *dap*A gene that codes for dihydrodipicolinate synthase in *Corynebacterium glutamicum* resulted in 35 % higher overproduction of L-lysine compared to the parent strain [129]. Another option for strain improvement is the transformation of *dap*A gene together with a *lys*C gene, coding for aspartate kinase with decreased feed back inhibition in *Corynebacterium glutamicum* [130].

In fed-batch culture and under appropriate conditions the favorable mutants for lysine production are able to reach final concentration of about 120 g/L L-lysine, calculated as hydrochloride [64]. Fermentation processes are performed in big tanks up to 500 m^3 size. An optimized feeding strategy practiced with a computer aided process control system may enable high conversion yield and productivity in large scale fed-batch cultivation [131]. Apart from the specific fermentation know how, inoculation, sterilization, and feeding strategy the recovery process and the quality of the product both can be decisive factors to guarantee competitiveness. The conventional route of lysine downstream processing is characterized by:

Removal of the bacterial cells from fermentation broth by separation or ultrafiltration

Absorbing and then collecting lysine in an ion exchange step

Crystallizing or spray drying of lysine as L-lysine hydrochloride

An alternative process consists of biomass separation, concentration of the fermentation solution, and filtration of precipitated salts. The liquid product contains up to 50 % L-lysine base, that is stable enough to be marketed [132]. In the 1990's, a new concept for lysine production was introduced. Here the lysine containing fermentation broth is immediately evaporated, spray-

dried, and granulated to yield a feed-grade product, which contains lysine sulfate. Its lysine content correspond to that of a material which contains to at least 60 % of L-lysine hydrochloride [133, 134]. The process avoids any waste products usually present in the conventional L-lysine hydrochloride manufacture.

3.2.12. D,L-Methionine and L-Methionine

L-Methionine and its antipode D-methionine are of equal nutritive value, thus the racemate can directly be used as feed additive.

The most economic way for production of D,L-methionine is the chemical process based on acrolein, methyl mercaptan, hydrogen cyanide, and ammonium carbonate (see Fig. 5). β-Methylthiopropionaldehyde, formed by addition of methyl mercaptan to acrolein, is the intermediate that reacts with hydrogen cyanide to give α-hydroxy-γ-methylthiobutyronitrile. Treatment with ammonium carbonate leads to 5-(β-methylthioethyl)hydantoin that is saponified by potassium carbonate giving D,L-methionine in up to 95 % yield, calculated on acrolein [135].

Figure 5. Degussa process for production of L-methionine

The production method of choice for L-methionine is still the enzymatic resolution of racemic *N*-acetyl-methionine using acylase from *Aspergillus oryzae*. The production is carried out in a continuously operated fixed-bed or enzyme membrane reactor [136].

Alternatively, L-methionine may be produced by microbial conversion of the corresponding 5-substituted hydantoin. With growing cells of *Pseudomonas* sp. strain NS671, D,L-5-(2-methylthioethyl)hydantoin was converted to L-methionine; a final concentration of 34 g/L and a molar yield of 93 % have been obtained [137].

Biosynthesis of L-methionine and its regulation in bacteria is well known. Although some promising concepts, for example utilization of sulfate, sulfite, or thiosulfate as sulfur sources for microbes have been suggested [138], it was not possible so far to develop strains that are able to excrete remarkable amounts of L-methionine into the culture medium.

3.2.13. L-Phenylalanine

Several chemical, biocatalytic, and fermentation methods for producing L-phenylalanine have been developed, some of which are of industrial significance (see Fig. 6).

In previous large-scale production processes for L-phenylalanine two enzymatic methods were applied:

1) Resolution of *N*-acetyl-D,L-phenylalanine by carrier-fixed microbial acylase: This process provided pharmaceutical-grade L-phenylalanine, but suffered from the disadvantage that the D-enantiomer had to be racemized and recycled.
2) Stereoselective and enantioselective addition of ammonia to *trans*-cinnamic acid, catalyzed by L-phenylalanine ammonia lyase (PAL, EC 4.3.1.5): PAL-containing *Rhodotorula rubra* was used in an industrial process [139] to supply L-phenylalanine for the first production campaign of the sweetener aspartame. When continuously operated in an immobilized whole cell reactor, the bioconversion reached concentration up to 50 g/L L-phenylalanine at a conversion of about 83 % [140]. Other processes started from phenylpyruvate with L-aspartic acid as amine donor using immobilized cells of *Escherichia*

Figure 6. Asymmetric syntheses for production of L-phenylalanine

coli [141] or from α-acetamidocinnamic acid and immobilized cells of a *Corynebacterium equi* strain [142]. In both cases L-phenylalanine concentrations up to 30 g/L and more (molar yields as high as at least 98 %) were reached.

However, fermentation processes based on glucose-consuming L-phenylalanine overproducing mutants of *E. coli* and coryneform strains turned out to be more economical. The biosynthetic pathway for aromatic amino acids in bacteria is strictly regulated [143]. L-Phenylalanine is formed in ten enzymatic steps starting from erythrose-4-phosphate and phosphoenolpyruvate. The biosynthesis is governed by the first key enzyme 3-deoxy-D-arabinoheptulosonate-7-phosphate synthase (DAHPS) which is inhibited by both L-phenylalanine and L-tyrosine (by acting on the enzyme itself) and repressed by L-tyrosine (by acting on the according gene of the DNA). The other important enzyme is prephenate dehydratase (PDT) also inhibited by L-phenylalanine, but stimulated by L-tyrosine. To overcome these regulatory mechanisms either auxotrophs of *Corynebacterium glutamicum* have been constructed or L-phenylalanine analogues, e.g., 4-aminophenylalanine and 4-fluorophenylalanine, have been applied. The latter variant leads to resistant mutants of *Brevibacterium flavum* or *lactofermentum* [144]. These auxotrophic and regulatory mutants are able to produce more than 20 g/L of L-phenylalanine in a medium containing 13 % glucose. Similar results can be obtained by tyrosine auxotrophic regulatory mutants of *E. coli* [145]. With recombinant DNA techniques it was possible to improve overproducing strains of coryneform bacteria as well as of *E. coli.* Amplification of a deregulated DAHPS gene was achieved in a phenylalanine producer of *Brevibacterium lactofermentum* [146]. For optimal production of L-phenylalanine in fed-batch cultivation the critical specific glucose uptake rate has to be controlled. The specific feed rate during fermentation has to be adjusted below a critical limit, since otherwise the *E. coli* producer will be forced to excrete acetate [147]. A suitable profile of the specific glucose feed rate prevents acetate formation and leads to improved L-phenylalanine production with a final concentration up to 46 g/L and a corresponding yield of 18 %. L-Phenylalanine is recovered from the fermentation broth either by two-step crystallization or by an ion-exchange resin process. The preferred cell separation technique is ultrafiltration; and the filtrates may be treated with activated carbon for further purification. Instead of ion-exchange resins nonpolar, highly porous synthetic adsorbents are recommended to remove impurities [148, 149]. An alternative process in which a cell separator is integrated in the fermentation pa rt, thus allowing cell recycling, was suggested for L-phenylalanine production and may lead to prospective developments [150].

3.2.14. L-Proline

L-Proline is still produced to a small extent by isolation from protein hydrolysates, but today direct fermentation using analogue-resistant mutants of coryneform bacteria or *Serratia marcescens* is an economic alternative production method [151]. An isoleucine auxotrophic mutant of *Brevibacterium flavum* having resistance to sulfaguanidine and D,L-3,4-dehydroproline (DP) is able to accumulate 40 g/L L-proline. *Brevibacterium flavum* AP113 is claimed to produce 97.5 g/L L-proline; this mutant is characterized by isoleucine auxotrophy, resistance to DP, and osmotic pressure and incapable to degrade L-proline [66]. A proline oxidase-less strain of *Serratia marcescens*, having resistance to DP, thiazoline-4-carboxylate and azetidine-2-carboxylate, overproduces 58.5 g/L L-proline into the culture medium [152]. By amplification of the genes *pro*A and *pro*B in this type of regulatory mutant, a construct was obtained which yields 75 g/L L-proline [153].

3.2.15. L-Serine

L-Serine is obtained by microbial/ enzymatic conversion of glycine using immobilized resting cells or crude cell extracts. *Hyphomicrobium* strains possess the serine pathway and are able to produce L-serine from methanol and glycine. Methanol is oxidized by methanol dehydrogenase to formaldehyde which in turn is converted in an aldol-like reaction with glycine to L-serine. The reaction is catalyzed by serine hydroxymethyltransferase (SHMT) [154]. *Hyphomicrobium* sp. NCIB10099 was found to produce 45 g/L L-serine from 100 g/L glycine and 88 g/L methanol in three days [155]. In an enzyme bioreactor with a feedback control system a crude extract from *Klebsiella aerogenes* containing SHMT has been used to synthesize L-serine from glycine and formaldehyde in the presence of tetrahydrofolic acid and pyridoxal phosphate. In this bioreactor a serine concentration of 450 g/L with an 88 % molar conversion of glycine at a volumetric productivity of $8.9\,g\,L^{-1}\,h^{-1}$ could be achieved under optimized conditions [156]. With whole cells of *Escherichia coli* MT-10350 L-serine is produced by treatment of an oxygenated aqueous glycine solution (485 g/L) with aqueous formaldehyde for 35 h at 50 °C in a molar yield of 89 % based on glycine [157]. Extraction of protein hydrolysates is used to a smaller extent.

3.2.16. L-Threonine

Up to the end of the 1980s, L-threonine was mainly used for medical purposes, in amino acid infusion solutions and nutrients. It was manufactured by extraction of protein hydrolysates or by fermentation using mutants of coryneform bacteria in amounts of several hundred tons per year worldwide. The production strains were developed by classical breeding. They were auxotrophic and resistant to threonine analogues such as α-amino-β-hydroxyvalerate (AHV), and reached product concentrations up to 20 g/L. These strains possessed deregulated L-threonine pathways with feedback inhibition-insensitive aspartate kinase and homoserine dehydrogenase [158, 159]. In the 1990s strain developments, using both conventional methods and recombinant DNA techniques, have been very successful. Potent classically selected mutants suggested for industrial production are the species *Brevibacterium flavum*, *Providentia rettgeri*, *Serratia marcescens*, and *Escherichia coli.* However, in the competition between the favorable candidates, strains of *Escherichia coli* proved to be superior to other bacteria. Although the pathway of L-threonine biosynthesis in *Escherichia coli* is much more regulated than that in *Corynebacterium glutamicum*, new *Escherichia coli* strains with excellent yields and productivity in threonine formation could be constructed by genetic engineering. L-Threonine is successfully marketed as feed additive with a worldwide demand of more than 10 000 t/a. Production strains are based on *Escherichia coli* K-12 constructs harboring plasmids containing the *thr* operon that consists of the genes *thr*A, *thr*B, and *thr*C [160]. Further improvements resulted in strains capable to accumulate more than 80 g/L in about 30 h with a conversion yield of more than 40 % [161]. The strain stability could be further improved, for example by integrating the threonine operon into the chromosome [162]. The recovery of feed-grade L-threonine is rather simple. After fermentation is completed, cell mass is removed by centrifugation or ultrafiltration, the

filtrate is concentrated, depigmentated and L-threonine isolated by crystallization [163].

3.2.17. L-Tryptophan

L-Tryptophan is one of the limiting essential amino acids required in the diet of pig and poultry. A mature and growing market for L-tryptophan as feed additive is in development,based on improved microbiological processes, and production has increased to several thousand tons per year. The most attractive production processes for tryptophan are based on microorganisms used as enzyme sources or as overproducers:

Enzymatic production from various precursors
Fermentative production from precursors
Direct fermentative production from carbohydrates by auxotrophic and analogue resistant regulatory mutants

L-tryptophan is synthesized from indole, pyruvate, and ammonia by the enzyme tryptophanase [164] or from indole and L-serine/D,L-serine by tryptophan synthase [165, 166]. Although production in enzyme bioreactors is quite efficient and concentrations of L-tryptophan up to 200 g/L could be achieved by condensation of indole and L-serine [167], these process variants were not economic due to the high costs of the starting materials. The microbial conversion of biosynthetic intermediates such as indole or anthranilic acid to L-tryptophan has also been considered as alternative for production. Whereas indole consuming mutants of *Corynebacterium glutamicum* produced about 10 g/L L-tryptophan [168], strains of *Bacillus subtilis* and *Bacillus amyloliquefaciens* reached final concentrations > 40 g/L L-tryptophan with anthranilic acid as carbon source [168, 169]. The process with anthranilic acid as precursor has been commercialized in Japan. However, the manufacturer using genetically modified strains derived from *Bacillus amyloliquefaciens* IAM 1521 was forced to stop L-tryptophan production. L-Tryptophan produced by this process was stigmatized because of side products found in the product causing a new severe disease termed eosinophilia-myalgia syndrome (EMS) [170]. One of the problematic impurities, "Peak E", was identified as 1,1′-ethylidene-*bis*-(L-tryptophan), a product formed by condensation of one molecule acetaldehyde with two molecules of tryptophan [171].

In other processes, i. e., direct fermentation using overproducing mutants and carbohydrates as carbon sources, formation of such impurities does not occur. In the 1990s striking progress has been made in the development of auxotrophic and deregulated mutants of *Brevibacterium flavum*, *Corynebacterium glutamicum*, and *Bacillus subtilis*. The biosynthesis of L-tryptophan and its regulation have been reviewed in detail for the different species [172–174]. The precise knowledge about the structure of the *trp* operon in *Escherichia coli* comprising the *trp* promoter and the genes *trp*E, *trp*D, *trp*C, *trp*B, and *trp*A which are coding for the enzymes anthranilate synthase (AS), phosphoribosyl anthranilate transferase (PRT), indole glycerol phosphate synthase (IGP) and tryptophan synthase (TS), respectively, was the benefit for further strain improvements.

Thus recombinant DNA techniques have been used to increase the capability of overproduction especially in strains of *Corynebacterium glutamicum* and *Escherichia coli*. One concept was realized successfully by amplification of *trp* operon genes together with *ser*A which codes for phosphoglycerate dehydrogenase. This key enzyme in L-serine biosynthesis should provide enough L-serine in the last step of L-tryptophan formation. Production strains are able to accumulate 30–50 g/L L-tryptophan with yields higher than 20 % based on carbohydrate. Isolation of L-tryptophan is still a major issue, because the amino acid is sensitive to oxygen and heat [167]. However, at a typical production concentration of 50 g/L, more than half of the L-tryptophan product crystallizes from the medium [68, 175].

3.2.18. L-Tyrosine

L-Tyrosine was, until recently, produced exclusively from protein hydrolysates. Its low solubility in water enables a quite simple isolation of the amino acid. Enzymatic catalysis using a b-tyrosinase (tyrosine-phenol lyase) from *Erwinia herbicola* gives tyrosine by a three-component synthesis from phenol, pyruvate, and ammonia.

This process has been commercialized for the enzymatic synthesis of the drug L-DOPA, where phenol is replaced by catechol [54]. L-Tyrosine is formed in nature as part of the shikimic acid pathway, as are L-phenylalanine and L-tryptophan. Recombinant DNA technology has been used to develop strains of *Corynebacterium glutamicum* that are specific for L-tyrosine, and production yields of 20–25 g/L have been obtained [175].

3.2.19. L-Valine

L-Valine is produced industrially in pharmaceutical quality by enzymatic resolution of *N*-acetyl-D,L-valine. Using direct fermentation the branched-chained amino L-valine can be produced by either α-aminobutyric acid-resistant mutants of *Serratia marcescens* or by 2-thiazolealanine-resistant coryneform strains [176]. *Brevibacterium lactofermentum* AJ12341 produces 39 g/L L-valine (28 % yield) [177].

4. Biochemical and Physiological Significance

The biosynthesis of amino acids begins with atmospheric nitrogen, which is reduced to ammonia by bacteria and plants. Ammonia is used by plants, by bacteria, and, to a limited extent, by ruminants as a raw material for amino acids. Amino acids, in turn, serve as starting materials for the synthesis of proteins and a variety of other nitrogen-containing compounds, such as the purine and pyrimidine bases in nucleic acids. Bacterial degradation leads, once again, to ammonia and nitrogen [178].

Figure 7. The transamination of amino acids

α-Ketoglutaric acid plays the central role in the assimilation of ammonia. Its transamination product, glutamic acid, in turn, can provide its amino group for the synthesis of other amino acids, e.g., alanine (Fig. 7).

Humans, animals, and some bacteria are incapable of synthesizing all the necessary amino acids in their own intermediary metabolism; i.e., they are heterotrophs and are therefore dependent on the biosynthetic capability of plants. Proteins that are consumed as foods by humans and animals are hydrolyzed to amino acids by the digestive enzymes. The amino acids are resorbed in the upper part of the intestine and enter the liver by way of the portal vein. The liver is the central organ for metabolism and homoeostasis of the plasma amino-acid level. The body's various requirements are met from the pool of free amino acids (Fig. 8), ca. 50 g in adult humans.

Figure 8. The amino acid pool and functions of amino acids in the intermediary metabolism

The lion's share of the amino acids ($\approx$ 300 g/d for adults) is required for synthesis of proteins [179]: structural proteins, enzymes, transport proteins, and immune proteins. Additionally, amino acids are required for the synthesis of oligopeptides and polypeptides that fulfill regulatory functions in the body, i.e., hormones.

Some amino acids or their metabolites are directly active as hormones or facilitate the transmission of nerve impulses (neurotransmitters), e.g., serotonin. Furthermore, there are amino acids that serve special functions, such as methionine, which is a methyl group donor. Finally, a series of amino acids serves as precursors for the biosynthesis of other structures. For example, glycine is used in the construction of the porphyrin skeleton. Amino acids are metabolized to produce energy in the case of a protein-deficient or a protein-excess diet.

The free amino acids in the amino acid pool undergo numerous transformations (Fig. 9), involving transamination and oxidative deamination, by which other amino acids can be synthesized. The α-keto acids are intermediates and in addition allow amino acids entrance into the carbohydrate (through pyruvate) and fatty acid (through acetylcoenzyme A) metabolisms. A distinction is therefore drawn between glucogenic and ketogenic amino acids.

Figure 9. Intermediary metabolism of amino acids (simplified)

D-Amino acids occur in the cell pool of plants and gram-positive bacteria and as building blocks in peptide antibiotics and bacterial cell walls [10, 14]. They do not occur in human or animal metabolism; proteins are made exclusively of L-amino acids. The traces of D-amino acids detected in metabolically inert protein (teeth, eye lenses) are believed to originate from racemization. Orally ingested D-amino acids are resorbed from the intestinal lumen more slowly than the L-form. The D-enantiomers cannot be utilized or can be utilized only to a slight extent as essential amino acids [180]. The one important exception is D-methionine. Animals and adult humans convert D-methionine into L-methionine by transamination. The α-keto acid of methionine is an intermediate. Otherwise, D-amino acids are degraded with the help of D-amino acid oxidases [181] to be used as an energy source [182].

The major end products of amino acid metabolism are urea, uric acid, ammonium salts, creatinine, and allantoin. The loss of nitrogen via these metabolites stabilizes at about 22 g protein per day after a few days on a protein-free diet.

Inborn disorders in amino acid metabolism [183] can lead to marked alterations in the excretion profile. These disorders usually take the form of an enzyme or transport deficiency [178, 184]. The most common example is phenylketonuria, a disruption of the normal metabolic pathway from phenylalanine to tyrosine caused by severe limitation in the activity of the phenylalanine hydroxylase [185].

Humans and animals are not capable of producing all the required L-amino acids in their intermediary metabolism. Therefore, they are dependent on an external source of these *essential* amino acids (Table 4). In situations of increased requirements (rapid growth, stress, trauma), histidine and arginine also become essential for humans. Cysteine and tyrosine may be essential for infants during their first few weeks, because their intermediary metabolism does not yet function well enough to produce these from methionine and phenylalanine in sufficient quantities.

5. Uses

The uses of amino acids have been treated in review articles [19, 186–189].

5.1. Human Nutrition

In addition to their nutritive value, amino acids are important flavor precursors and taste enhancers. In foods for humans, the flavor uses of amino acids represent the dominant factor in

[c] Cys can partly cover the total *S*-amino acid requirement.
[d] Tyr can partly cover the total aromatic amino acid requirement.

total market value. In animal nutrition, amino acids are used almost exclusively for their nutritive value.

Addition of small amounts of amino acids to improve the nutritive value of proteins is known as supplementation. Both supplementation and the combination of proteins with complementary amino acids are used to increase the biologic value of proteins. Usually the supply of at least one of the essential amino acids lies below the requirement. This, the limiting amino acid, determines what percentage of the protein (or, more precisely, its amino acids) can be used to meet the body's amino acid requirements. In most cases, methionine is the first limiting amino acid. Sometimes it is lysine; now and then it is both together.

The contents of essential amino acids found in several animal and vegetable foodstuffs are compiled in Table 5. Considerable variations may be present in the amino acid contents of a given foodstuff.

The published requirements for the individual essential amino acids differ. The values (Table 6) usually contain safety factors and therefore are higher than the minimum requirement. Requirement values were first determined by Rose [192]; those published by Hegsted [193] are considered the most reliable at present. The amino acid requirement pattern suggested by the FAO/WHO [194] is considered optimal for the greatest part of the population.

The "average safe level of daily protein intake for men and women," based on these amino acid requirement figures, is given as 0.55 g/kg body weight. The acute daily protein requirement, however, varies between 0.5 and 2.5 g/kg with age and constitution [195]. The Deutsche Gesellschaft für Ernährung (DGE) recommends a daily consumption of 0.9 g/kg body weight [196, 197]. The Committee on Dietary Allowances, Food and Nutrition Board of the National Academy of Sciences (NAS), USA, cites 0.8 g/kg as a desirable level of daily protein consumption [198, 199].

5.1.1. Supplementation

In general, animal protein contains the essential amino acids in larger quantities and in a more favorable ratio than vegetable protein, which is often deficient in essential amino acids. Lysine is the first limiting amino acid in wheat, rye, barley, oats, maize, and millet, whereas methionine is the first limiting amino acid in meat, milk, soybeans, and other beans. The second limiting amino acids are usually threonine (wheat, rice) and tryptophan (maize, rice, casein). The limiting amino acids for several foodstuffs are listed in Table 7.

Improving the biologic value of vegetable protein in human nutrition is practiced for economic and dietary reasons. Combining different protein types is not always practical. Often a complementary protein is unavailable, too expensive, or not of acceptable taste. In these cases supplementation with amino acids is the simplest method of increasing the biologic value of

proteins. There is a monumental volume of literature on the subject of amino acid supplementation [200–207].

The biologic value is an important criterion for the evaluation of proteins or amino acid mixtures. It can be determined experimentally [208, 209]. In principle, all methods measure the ability of the nutritional protein to replace body protein. Table 8 lists the biologic values of nutritional proteins as determined by the minimum requirement [195]. Whole egg protein is the reference in this scale.

Table 7. Limiting amino acids in foodstuffs

Proteins	First limiting amino acid	Second limiting amino acid(s)
Peanut	Thr	Lys and Met
Fish	Met	Lys
Casein	Met	Trp
Torula yeast	Met	
Sesame	Lys	
Skim milk	Met	
Beans	Met	
Sunflower seed	Lys	Thr
Soy protein	Met	Lys
Wheat	Lys	Thr
Rice	Lys	Thr and Trp
Rye	Lys	Thr and Trp
Gelatin	Trp	
Maize	Lys	Trp and Thr

Another scale of evaluation is the protein efficiency ratio (PER). This is the daily weight gain of young animals, usually rats, under standard feeding conditions (see Table 8). In an improved method, the animals are fed diets of various protein levels, and the protein efficiency is then determined using regressional analysis.

The net protein retention (NPR) method and the net protein utilization (NPU) method are more accurate than the PER method because they consider the protein (NPR) or total nitrogen (NPU) requirement for maintenance. The "chemical score," in which the availability of the amino acids is not considered, is suitable for a gross estimation of the biologic protein quality. In this method the amino acid content is determined analytically and compared with the amino acid pattern of a reference protein, e.g., the FAO/WHO provisional scoring pattern (Table 9). This method provides an immediate picture of the size of amino acid gaps and the sequence of limiting amino acids.

$$\text{Score} = \frac{\text{Content of amino acid in test protein}}{\text{Content of amino acid in reference protein}} \times 100$$

Table 9. FAO/WHO provisional scoring pattern 1973 [194]

Amino acid	g/100 g protein
L-Isoleucine	4.0
L-Leucine	7.0
L-Lysine	5.5
L-Methionine + L-cystine *	3.5
L-Phenylalanine + L-tyrosine **	6.0
L-Threonine	4.0
L-Tryptophan	1.0
L-Valine	5.0
Total	36.0

* Cys can partly cover the total *S*-amino acid requirement.
** Tyr can partly cover the total aromatic amino acid requirement.

As can be seen in Table 10, addition of ca. 0.1–0.5 % of the limiting amino acid to such basic foodstuffs as wheat, rice, maize, and soy-

Table 8. Protein quality of food and minimum requirements (human)

Food	Biologic value $g\ kg^{-1}\ d^{-1}$ [195]	Minimum requirement *, ratio (rat) [195]	Protein efficiency [190]
Whole egg	100	35	3.92

Extruded soy protein (10%)					1.99
				0.23	2.62

* Reference protein: casein, PER=2.50.

beans raises the protein efficiency in rat growth tests impressively.

Clinical studies [212–214] and field trials have solidified the evidence of the benefits to human nutrition of amino acid supplementation [215–218]. However, the general supplementation of basic foodstuffs, such as bread and rice, is not yet practiced extensively. In dietary nutrition, however, supplementation already plays an important role (Table 11).

Some infants exhibit lactose or cow's milk protein incompatibility. The formulas marketed for this condition often are based on isolated soybean protein and are supplemented with L-methionine to increase the biologic value. The advantageous effects of L-methionine supplementation on the physical development of infants has been demonstrated in a series of clinical studies [219, 220]. Additionally, the food for pregnant and nursing women, seniors, overweight persons, and athletes can also be supplemented. Extruded soy protein, which is used in large quantities as a meat extender and vegetarian meat substitute, can be supplemented with *N*-acetyl-L-methionine [221].

5.1.2. Flavorings, Taste Enhancers, and Sweeteners

Free amino acids occur in almost all protein-based foods. In some foods their concentration is several percent. Foodstuffs having a relatively high concentration of free amino acids include fruit juices [222], cheese [223, 224], beer [225], and seafood [226]. Approximately 85 % of the free amino acids in orange juice is proline, arginine, asparagine, γ-aminobutyric acid, aspartic acid, serine, and alanine [227].

Amino acids are relatively tasteless. Nonetheless, they contribute to the flavor of foods. They have characteristic synergistic flavor-enhancing and flavor-modifying properties, and they are precursors of natural aromas [228–230]. Amino acids and protein hydrolysates are therefore useful additives in the food industry. The sodium salt of L-glutamic acid (MSG) exhibits a particularly pronounced flavor-enhancing effect, leading to the introduction of a fifth human taste concept of *umami* [231], and has been recognized as a flavoring factor for seaweed, sake, miso, and soy sauce since 1908. The substance is used in concentrations of 0.1–0.4 % as an additive for spices, soups, sauces, meat, and fish, usually in combination with nucleotides [230]. In 2000, the existence of a specific receptor for umami was confirmed [232].

L-Cysteine especially enhances the aroma of onion [233] and is therefore used to rearomatize dried onions. Glycine, which has a refreshing, sweetish flavor, occurs abundantly in mussels and prawns. It is considered to be an important flavor component of these products. When used as an additive for vinegar, pickles, and mayonnaise, it attenuates the sour taste and lends a note of sweetness to their aroma. D,L-Alanine is used for the same purpose in the Far East [234]. Glycine is used to mask the aftertaste of the sweetener saccharin [235, 236].

The L- and D-amino acids usually exhibit pronounced flavor differences. Many L-enantiomers taste weakly bitter, whereas their optical antipodes, the D-amino acids, taste sweet [237–

Table 11. Amino acids in dietetic products

Protein/protein hydrolysate	Supplemented amino acid	Use	Indication
Cow's milk, casein, whey protein	L-Cyss and/or L-Lys · HCL	infant nutrition	adapted nutrition
Soy protein	L-Met	infant nutrition	lactose incompatibility and milk protein allergy
Casein/yeast	L-Lys · HCl	meal supplement	protein malnutrition, in place of conventional nutrition

239] (Table 12). For the most part, dipeptides and oligopeptides have bitter flavors. One of the few exceptions is the methyl ester of the dipeptide L-aspartyl-L-phenylalanine (Aspartame) [240, 241], which is 150–200 times sweeter than sucrose (→ Sweeteners).

Table 12. Tastes of L- and D-amino acids* [239]

	L-Amino acid	D-Amino acid
Alanine	sweet (12–18)	sweet (12–18)
Arginine	bitter	neutral
Asparagine	neutral	sweet (3–6)
Aspartic acid	acidic/neutral	acidic/neutral
Cysteine	sulfurous	sulfurous
Glutamine	neutral	sweet (8–12)
Glutamic acid	acidic/"glutamate-like"	acidic/neutral
Glycine	sweet (25–35)	sweet (25–35)
Histidine	bitter	sweet (2–4)
Isoleucine	bitter	sweet (8–12)
Leucine	bitter	sweet (2–5)
Lysine	sweet/bitter	sweet
Methionine	sulfurous	sweet/sulfurous (4–7)
Phenylalanine	bitter	sweet (1–3)
Proline	sweet/bitter (25–40)	neutral
Serine	sweet (25–35)	sweet (30–40)
Threonine	sweet (35–45)	sweet (40–50)
Tryptophan	bitter	sweet (0.2–0.4)
Tyrosine	bitter	sweet (1–3)
Valine	bitter	sweet (10–14)

* Threshold values for sweet taste in parenthesis, µmol/mL; the threshold value for sucrose is 10–12 µmol/mL.

The free amino acids are used widely in foodstuff technology as precursors for aromas and brown food colors [242]. The flavors are formed during foodstuff production, e.g., during the ripening of cheese [243, 244], the fermentation of alcoholic beverages [245, 246], or the leavening of dough [247, 248], or foodstuff cooking, e.g., frying, roasting, boiling, by the Maillard reaction between amino acids and reducing sugars (nonenzymatic browning) [228, 249, 250]. The Strecker degradation of amino acids plays a central role in this process. A broad spectrum of aroma-intensive, volatile compounds forms [251, 252]. The most important classes are aliphatic carbonyl compounds and heterocycles, such as furans, pyrones, pyrroles, pyrrolidines, pyridines, imidazoles, pyrazines, quinoxalines, thiophenes, thiolanes, trithianes, thiazoles, and oxazoles.

It is often possible to assign certain aromas to specific amino acids [252]. For example, the sulfur-containing amino acid cysteine is primarily responsible for the formation of meat flavor. Proline seems to be important for the aroma of bread crust. Phenylalanine, as well as the branched-chain amino acids leucine and valine, is important for the characteristic flavor of chocolate. Valine and leucine are also involved in the aroma of roasted nuts. Methionine plays a key role in the aroma of French fries. The flavors of such products as precooked foods, snack articles, and spices may be improved by addition of the proper Maillard aromas. One variation is adding the precursors of the Maillard aromas, i.e., amino acid plus sugar, to the foodstuff and allowing the fragrance to form in situ. Some aroma profiles that can be prepared from amino acids are compiled in Table 13.

Table 13. Amino acids for Maillard flavors *

Meat, poultry [253]	Cys, Cyss, Gly, Glu, Ala, Met, His, Ser, Asp, Pro
Bread, cracker, biscuit [247, 254]	Pro, Lys, Arg, Val, His, Leu, Glu, Phe, Asp, Gly, Gln
Chocolate, cocoa [255]	Leu, Phe, Val, Glu, Ala
Honey [256–258]	Phe
Cream, butter [259]	Pro, Lys, Ala, Gly, His
Nut, peanut [260]	Leu, Val, Ile, Pro, Glu, Gln, His, Phe, Asp, Asn
Potato [261]	Met
Tobacco [257, 262]	Asn, Arg, GABA, Gln, Ala, Gly, Orn, Glu, Asp, Leu, Val, Thr, Pro, Tyr, Phe

* Key amino acids underlined.

5.1.3. Other Uses in Foodstuff Technology

Amino acids are used in the foodstuff industry for purposes other than supplementation and flavoring. L-Cysteine, for example, is used by the baked goods and pasta industry as a flour additive [263, 264]. As a reducing agent, it relaxes

wheat gluten proteins (by cleavage of the disulfide linkages), homogenizes the dough, accelerates dough development, and improves the structure of the baked product, while allowing shorter kneading times.

Because they are capable of forming complexes with metals, amino acids act as antioxidants for fats and fat-containing foodstuffs [265]. This effect is strengthened by primary antioxidants, such as α-tocopherol. Melanoidines, which are formed during the Maillard reaction, are stronger antioxidants than the amino acids themselves [266]. Maillard products are also reported to be preservatives [267]. Glycine apparently exhibits a special preservative effect [268].

There has been a recent upsurge in the sale of sports drinks and "energy bars", foodstuffs containing supplements with selected amino acid. These drinks were originally designed for performance athletes, but are now in widespread use, and the market is growing rapidly [269]. Amino acids used in functional beverages and foods include creatine, which is intended to help build muscle; the branched-chain amino acids L-isoleucine, L-leucine, and L-valine, which are important components of cell membrane proteins and assist synthesis of body protein and reduce central fatigue; and L-arginine, which is a regulatory agent for the circulation (production of NO). These amino acids have a higher rate of uptake in the body than protein, and improve muscle strength and recovery after exercise [270].

5.2. Animal Nutrition

The use of amino acids for the nutrition of monogastric animals is based on the same foundation as the supplementation of human foodstuffs and the clinical experience with humans. In practice, the enrichment of animal feeds and formulated feeds with amino acids, especially methionine and lysine, represents far greater quantities than does human nutrition. By supplementing feeds or formulated feeds with the first limiting amino acid an obvious cost reduction can be achieved, while maintaining the quality of the ration [271].

Of the ca. 20 amino acids found in feed protein, about one half are essential for monogastric animals (see Table 4). Most natural feeds are relatively poor in methionine and lysine (Table 14). The requirement of our livestock, however, is comparatively high [272].

When formulating a feed mix for a given animal type, the manufacturer has two choices for meeting the requirement of a particular amino acid. He may use either an excess of feed protein that contains large amounts of this amino acid or a minimum of natural protein and supplement it with synthetic amino acid. Because methionine, lysine, and threonine are commercially available and inexpensive, they are often used in formulated feed. L-Tryptophan, which in many cases is the third or fourth limiting amino acid, is becoming more popular as an ingredient for feed supplements, particularly for pigs.

Amino Acids Content of Feedstuffs. Effective supplementation requires an exact knowledge of the natural amino acid content of both the individual feedstuffs and the formulated feed mix: the desired rates of supplementation must always be capable for being measured analytically. Ion-exchange and high-pressure liquid chromatography are reliable and proven methods for this.

The amino acid contents of individual feedstuffs are published internationally in a large series of tabulations (see, e.g., Table 14). However, such data must be current and reliable.

Amino Acid Requirements of Livestock. Determining amino acid requirement of animals requires difficult, time-consuming experiments. The values derived from these experiments are not constants valid for all times but vary depending on environmental (heat stress, disease), genetic (sex, breed), and dietary factors (protein level, energy level, feed intake). There are essentially three methods for determining these requirements: carcass or milk analysis, synthetic rations, and semisynthetic rations.

For the first method, the amino acid content of a carcass is taken as a first-order approximation to the amino acid requirement of an animal. The same method can be applied for young suckling mammals by analyzing the amino acid content of the milk.

In the second method, the test animal is fed a synthetic mixture of all amino acids, along with an otherwise balanced ration (control group). The requirement for a single amino acid is determined by reducing its content in the diet to zero

Table 14. Amino acid composition of feedstuffs, wt % [272, 273]

Feedstuff	Dry matter	Crude protein	Met	Met+Cys	Lys	Thr	Trp	Arg	Leu	Ile	Val	His

* Crude Protein

and from there on supplementing it stepwise up to an amount where the animal performs as well as the control group.

The third and most commonly used method is that a basal diet consisting of typically used feeds is formulated to be deficient in one amino acid but adequate in all other nutrients. To this basal diet graded levels of the amino acid in question are added until the performance of the animal approaches a maximum. The response in growth to stepwise increasing of amino acid supplementation follows the law of diminishing returns and can be described best by an exponential function.

Amino acid recommendations and requirements vary between species and for each species with age. There are several physiological reasons for that:

The various proteins deposited in the animal's body differ considerably in their amino acid composition. In poultry, for example, the proportion of lysine is much higher in muscle protein than in feather protein. In contrast, methionine and cystine are required in a higher percentage for the formation of feather protein and for maintaining metabolic functions than for muscle protein.

Not only the amino acid composition of the different proteins varies but also the quantity of each protein deposited in the animal changes with age. The daily accretion of muscle protein increases up to a certain age depending on the species and declines thereafter. The daily protein requirement for metabolic functions rises continually as the animal grows. Another reason for amino acid recommendations changing with age is the fact that young animals have a high potential for growth but at the same time a relatively small feed intake capacity which requires a high nutrient density in the diet.

Table 15. Amino acid recommendations, wt %, for poultry [273] and pigs [274, 275]

Species	Metabolizable energy, MJ/kg	Crude protein	Met	Met+ Cys	Lys	Thr	Trp
Broiler							
Starter	12.7	21	0.57	0.92	1.27	0.80	0.20

Lactating	9.8	16.5	0.36	0.65	1.00	0.70	0.20
Pregnant	8.9	12.5	0.23	0.42	0.70	0.46	0.14

The amino acid recommendations for domestic monogastric animals are listed in Table 15.

Economics of Amino Acid Supplementation. The purpose of modern, formulated feed mixes is to meet all nutritional requirements of the animal at a minimum cost, and amino acids and proteins are usually among the most expensive components of a feed mix. The performance of a feed mix is measured primarily by feed utilization and weight gain. Both feed utilization and weight gain, as well as other factors such as laying performance or feather or hair growth, are directly dependent on a sufficient supply of amino acids. Methionine and lysine play the major roles. Methionine in the form of D,L-methionine and lysine in the form of L-lysine · HCl are used in place of or as a supplement to natural methionine and lysine sources [276].

Linear programming is the method of choice for simultaneously optimizing a ration and minimizing cost [277]. This method allows simultaneous consideration of all demands that are made on the ration. A prerequisite is exact data on the nutrient content of all available feedstuffs and additives as well as their prices and availabilities. Additionally, the restrictions, i.e., the dietary requirements that the ration has to fulfill, must be known. Table 16 shows two examples of feed mixes formulated by the linear programming method commonly used.

Protein and Amino Acid Digestibilities of Feed Ingredients. The nutritive value of protein for monogastric animals is determined not only by the amino acid composition of the diet but also by digestibility of the individual amino acids, in particular the amino acids likely to be limiting. Over the last decades, considerable research has been carried out that demonstrates large differences in amino acid digestibilities between feeds.

Amino acid digestibilities can be determined according to the ileal or fecal analysis method. The fecal analysis method measures the amount of each amino acid consumed and excreted in feces. The amino acid digestibilities determined according to the ileal analysis method are calculated based on the intake and amount of each amino acid passing at the end of the distal ileum. The ileal analysis method should be considered as an improvement on the fecal analysis method, since the protein or amino acid absorbed in the large intestine make little or no contribution to the protein status of the animal. The ileal analysis method is also very sensitive to differences in amino acid digestibilities, as these result from processing conditions or from inherent differences between samples of the same feedstuff. Digestibilities measured over the entire digestive tract may be altered by resident bacteria. The bacteria may break down some of the amino acids, convert them to other amino acids, or even produce new amino acids. Measuring ami-

Table 16. Two examples of formulated feeds

Broiler feed composition, wt %		Pig fattening feed composition, wt %	
Yellow corn	28.00	Feed grain (barley, wheat, corn)	35.00
Wheat	20.00	Soybean meal (44 % crude protein)	19.00
Soybean meal (48 % crude protein)	30.00	Tapioca meal	20.00
Tapioca meal	10.00	Corn gluten feed	15.00
Fat	7.00	Meat and bone meal (45 % crude protein)	3.00
Meat and bone meal (45 % crude protein)	3.00	Fat	3.00

	100.00	D,L-Methionine	0.07
			100.00

no acids excreted in the feces will not reflect unabsorbed amino acid, but rather unabsorbed amino acids after possible alteration by the bacteria.

Amino acid digestibility values from the literature, determined with the ileal analysis method (Table 17) show large differences in amino acid digestibilities between feeds and among different samples of the same feed.

The differences in amino acid digestibility of feeds can be attributed to various factors. These include, e.g., fiber levels, heat damage during processing and the presence of antinutritional factors that interfere with nutrient digestion and utilization.

Studies have clearly shown improvements in diet formulation practices, when diets are formulated on the basis of ileal digestible rather than on supply of limiting amino acids. This holds especially true when a good quality protein supplement is replaced by protein supplement(s) of lower quality combined with supplementary amino acids. In consequence, amino acid requirements should be expressed as ileal digestible, rather than as total amino acid requirements.

Amino Acids as a Measure to Reduce the N-Output from Livestock Production. Animal production accounts for a significant portion of nitrogen containing compounds released into the environment. In areas with intensive livestock production this might result in environmental problems, especially if N-requirements for crop fertilization and N-output from livestock production get out of balance. In this case nitrogen containing compounds are released into the surface and ground water where they accumulate.

The total amount of nitrogen produced is dependent on both the average number of animals per unit available on and the efficiency of conversion of feed protein into body protein. This efficiency is often impaired due to diets that are not balanced for the specific amino acid requirements of the animal fed. The portion of protein that is fed without supplying an adequate mix of amino acids is thus excreted without being utilized by the animals. Meanwhile the animal's requirements for amino acids are well known which allows a reduction in the total protein content of diets as long as the diet is supplemented with amino acids in accordance with the animal's specific requirements. As a result, feed protein utilization is maximized and also water intake as a means to excrete excess nitrogen via the kidney is reduced.

In consequence the N-output from livestock production can be reduced down to 65 % when supplemental amino acids are used together with a reduction of the protein content of the diet.

5.3. Pharmaceuticals

The pharmaceutical industry requires amino acids at a rate between 2000 and 3000 t/a worldwide. More than half of this is used for infusion solutions. During the last few years the potential of amino acids and their derivatives as active ingredients for pharmaceuticals has been recognized clearly, and considerable growth can be predicted.

Table 17. Range of ileal digestibilities (%) of lysine, methionine, and threonine in different feeds for pigs modified from [274]

Amino acids	Lysine	Methionine	Threonine
Cereal grains			
Barley	65–79	72–88	64–76

5.3.1. Nutritive Agents

Infusion Solutions. Parenteral nutrition with L-amino acid infusion solutions is a well-established component of clinical nutrition therapy. A standard infusion solution contains the eight classical essential amino acids, the semiessential amino acids L-arginine and L-histidine, and several nonessential amino acids, generally glycine, L-alanine, L-proline, L-serine, and L-glutamic acid.

Also available are special infusion solutions tailored to the requirements of particular groups, such as newborn infants, seniors, or patients with an extreme negative nitrogen balance. Solutions rich in the branched-chained amino acids leucine, isoleucine, and valine and poor in methionine and aromatic amino acids are available for liver-disease patients. Solutions containing only essential amino acids are available for kidney patients. Enzymatic protein hydrolysates, which were used as infusion solutions until the 1980s have disappeared almost completely from the market. They were not available in the optimal composition, and there were often compatibility problems. Only pure, crystalline L-amino acids are used in modern infusion solutions. The solutions (up to 10 %), which also contain electrolytes in addition to amino acids, are sterile and pyrogen-free.

The simultaneous administration of carbohydrates is necessary for optimal utilization of the amino acids. Glucose is normally a separate infusion. Some commercially available amino acid infusion solutions contain an energy source in the form of sugar alcohols (sorbitol, xylitol), which do not enter into a Maillard reaction with the amino acids.

Normally, parenteral nutrition is only practiced over a limited time. In principle, however, total parenteral nutrition over many years is possible. In such a case, all essential nutrients (unsaturated fatty acids, vitamins, and trace elements) must be provided.

Elemental Diets. Enteral nutrition is also a means of providing the essential nutrients [278]. Elemental diets, which were developed originally for the astronauts [389], contain chemically defined nutritive components. In addition to free amino acids the mixtures generally contain carbohydrates, fats, minerals, and vitamins in a combination adapted to the requirements. In many cases, elemental diets are used as an alternative and supplement to parenteral nutrition. They have high nutritional value and are totally resorbable. They are largely independent of the digestive function of the pancreas and reduce the intestinal bacteria flora. Amino acid elemental diets generally are used in cases of anatomic, functional, or enzymatic defects [279].

Formula diets based on peptides are gaining ground as an alternative to elemental diets based on L-amino acids. According to [280], short-chained peptides are resorbed rapidly via a peptide transport system in the gut, therefore in a process that is independent of amino acid transport. Compositions of nitrogen-free amino acid analogues (keto acids and hydroxy acids) have come into use for the special case of kidney insufficiency (chronic renal failure).

Elemental diets or formula diets are administered orally or via a nasogastric tube directly into the gastrointestinal tract.

5.3.2. Therapeutic Agents

Many therapeutic agents are derivatives of natural or nonnatural amino acids. Examples are benserazide, captopril, and dextrothyroxine. They are described under keywords

such as → Spasmolytics, → Antihypertensives, → Antihypotensives, or → Thyrotherapeutic Agents. Only therapeutically useful amino acids and simple derivatives are treated here.

Amino Acids and Salts. The amino acids and their simple salts that are important therapeutic agents are compiled in Table 18. The proprietary names listed represent only a selection.

***N*-Acetylcysteine** [*616-91-1*], $C_5H_9NO_3S$, M_r 163.2, *mp* 109–110 °C, $[\alpha]_D^{20}$ + 5° (*c* = 3, H_2O), is a mucolytic and secretolytic agent. It is also indicated for the treatment of paracetamol poisoning.

N-Acetylcysteine is prepared by reaction of cysteine hydrochloride monohydrate with acetic anhydride in the presence of sodium acetate [281, 282].

Trade names: Exomouc (Bouchara), Fluimucil (Zambon) and numerous others [283].

Carbocisteine (carbocysteine) [*638-23-3*], *S*-carboxymethyl-L-cysteine, $C_5H_9NO_4S$, M_r 179.2, *mp* 204–207 °C (decomp.), $[\alpha]_D^{20}$ −34.0 to −36.0° (*c* = 10, H_2O), is used to treat disorders of the respiratory tract associated with excessive mucus.

Synthesis involves *S*-alkylation of L-cysteine with chloroacetic acid in the presence of sodium hydroxide [284, 285].

Trade names: Mucodyne (Sanofi-Aventis) and numerous others [283].

Fudosteine [*13189-99-5*], *S*-(3-hydroxypropyl)- L-cysteine, $C_6H_{13}NO_3S$, M_r 179.24, *mp* 198–202 °C, $[\alpha]_D^{20}$ −22° (*c* = 1, H_2O), was launched by Mitsubishi Pharma in 2001 for the treatment of bronchial hypersecretion.

Fudosteine is synthesized by condensation of L-cysteine with 3-bromopropyl alcohol in aqueous NaOH, or by condensation of L-cysteine with allyl alcohol by means of aqueous potassium persulfate [286].

Trade names: Cleanal, Spelear (Mitsubishi Pharma).

Levodopa [*59-92-7*], (*S*)−3-(3,4-dihydroxyphenyl)alanine, $C_9H_{11}NO_4$, M_r 197, *mp* 285.5 °C (decomp.), $[\alpha]_D^{20}$ −12.15° (*c* = 4 in 1 M HCl).

Levodopa is widely used for treatment of Parkinson's disease, most often in combination with peripheral decarboxylase inhibitors such as benserazide and carbidopa. For manufacture and trade names → Parkinsonism Treatment.

Trade names: Larodopa (Roche) and numerous others [283].

Mecysteine hydrochloride [*18598-63-5*], cysteine methyl ester hydrochloride, methyl L-2-amino-3-mercaptopropionate hydrochloride, $C_4H_{10}ClNO_2S$, M_r 171.66, *mp* 140–141 °C, is used in the treatment of disorders of the respiratory tract associated with excessive mucus. It is prepared by esterification of L-cysteine hydrochloride monohydrate with methanol in the presence of hydrogen chloride [287].

Trade names: Acthiol (Joullié, France), Actiol (Lirca, Italy), Visclair (Sinclair, UK), Aslos-C (Nissin, J), Epectan (Seiko, Japan), Moltanine (Tohok.-Tokyo Tanabe, Japan), Radcol (Nippon Universal, Japan), Sekinin (Tokyo Hosei, Japan).

Methiosulfonium chloride (iodide) [*1115-84-0*], L-methylmethionine sulfonium chloride, vitamin U, $C_6H_{14}ClNO_2S$, M_r 199.7; *mp* 134 °C (decomp.). Iodide [*3493-11-6*], $C_6H_{14}INO_2S$, M_r 291.1.

Table 18. Amino acids and their salts as drugs

Compound		Formula	M_r	Medical use	Trade names
L-Alanine	[*56-41-7*]	$C_3H_7NO_2$	89.09	parenteral nutrition, stimulant of glucagon secretion	
L-Arginine	[*74-79-3*]	$C_6H_{14}N_4O_2$	174.20	parenteral nutrition, stimulation of pituitary release of growth hormone and prolactin, stimulation of pancreatic release of glucagon and insulin	
L-aspartate	[*7675-83-4*]	$C_{10}H_{21}N_5O_6$	307.31	treatment of hyperammonemia	Argihepar, Laevil, Potentiator, Sargenor, Sorbenor
L-glutamate	[*4320-30-3*]	$C_{11}H_{23}N_5O_6$	321.34	treatment of hyperammonemia	Modumate
hydrochloride	[*1119-34-2*]	$C_6H_{15}ClN_4O_2$	210.66	treatment of hyperammonemia, electrolyte concentrate for i.v. solutions	Argivene, R-Gene, Polilevo
L-pyroglutamate		$C_{11}H_{21}N_5O_5$	303.27		
2-oxoglutarate	[*16856-18-1*]	$C_{11}H_{20}N_4O_7$	320.3	treatment of hepatic disorders	Leberam, Anetil, Argiceto, Eucol
L-Asparagine	[*70-47-3*]	$C_4H_8N_2O_3$	132.13	parenteral nutrition	
monohydrate	[*5794-13-8*]	$C_4H_{10}N_2O_4$	150.13		
D,L-Aspartic acid	[*617-45-8*]	$C_4H_7NO_4$	133.10		
magnesium, tetrahydrate	[*52101-01-6*]	$C_8H_{20}N_2O_{12}Mg$	360.54	cardiac agent, management of fatigue, mineral supplement	Magnesium Verla,
potassium, semihydrate	[*923-09-1*] (anhydrous)	$C_4H_6NO_4K \cdot 1/2\,H_2O$	180.20	cardiac agent, management of fatigue, mineral supplement	Trommcardin, Trophicard-Köhler
sodium, monohydrate		$C_4H_8NO_5Na$	173.10		
L-Aspartic Acid	[*56-84-8*]	$C_4H_7NO_4$	133.10	parenteral nutrition	
ferrous, tetrahydrate		$C_8H_2ON_2O_{12}Fe$	392.1	treatment of iron deficiency	Sideryl, Spartocine
magnesium, dihydrate	[*2068-80-6*]	$C_8H_{16}N_2O_{10}Mg$	324.52	management of fatigue and heart conditions	
potassium, semihydrate	[*1115-63-5*] (anhydrous)	$C_4H_6NO_4K \cdot 1/2\,H_2O$	180.20	management of fatigue and heart conditions	Magnesiocard, Corroverlan
sodium, monohydrate	[*3792-50-5*] (anhydrous)	$C_4H_8NO_5Na$	173.10	parenteral nutrition	
Betaine	[*107-43-7*]	$C_5H_{11}NO_2$	117.15		
citrate	[*17671-50-0*]	$C_{11}H_{19}NO_9$	309.27	lipotropic	Flacar, Panstabil
hydrochloride	[*590-46-5*]	$C_5H_{12}ClNO_2$	153.61	lipotropic, gastric acidifier	Aciventral, Acidol, Pesimuriat
monohydrate	[*17146-86-0*]	$C_5H_{13}NO_3$	135.15	lipotropic	Hepaderichol
L-Citrulline	[*372-75-8*]	$C_6H_{13}N_3O_3$	175.19	treatment of hepatic disorders	Polilevo
L-Cysteine	[*52-90-4*]	$C_3H_7NO_2S$	121.16	treatment of damaged skin, topically in ophthalmology, detoxicant	Reducdyn, Hepa-Loges, Irradian, Cicatrex, Felacomp
hydrochloride	[*52-89-1*]	$C_3H_8ClNO_2S$	157.62		Cheihepar, Choldestal
hydrochloride monohydrate	[*7048-04-6*]	$C_3H_{10}ClNO_3S$	175.64		
L-Cystine	[*56-89-3*]	$C_6H_{12}N_2O_4S_2$	240.30	parenteral nutrition, lipotropic agent, treatment of hair and nail damage	Cystin "Brunner", Gerontamin, Pantovipar, Priorin
L-Glutamic acid	[*56-86-0*]	$C_5H_9NO_4$	147.13	parenteral nutrition, dietary supplement, treatment of hyperammonemia	Aciglut, Glutamin-Verla
calcium, dihydrate	[*5996-22-5*]	$C_{10}H_{20}N_2O_{10}Ca$	368.2		Vivacalcium
hydrochloride	[*138-15-8*]	$C_5H_{10}ClNO_4$	183.54	gastric acidifier	Bioprotein-Holzinger, Pansan, Pepsalara
monosodium, monohydrate	[*142-47-2*] (anhydrous)	$C_5H_{10}NO_5Na$	187.13	flavoring and seasoning of food	
magnesium, tetrahydrate	[*19238-50-7*]	$C_{10}H_{24}N_2O_{12}Mg$	388.62	tonics, mineral supplements	Magnesium Verla, Glutergen
potassium, monohydrate	[*19473-49-5*] (anhydrous)	$C_5H_{10}NO_5K$	203.24	tonics, mineral supplements	

Table 18. (Continued)

Compound		Formula	M_r	Medical use	Trade names
magnesium, hydrobromide		$C_{10}H_{17}BrN_2O_8Mg$	397.5	tranquilizer	Psicosoma, Psychoverlan
L-Glutamine	[*56-85-9*]	$C_5H_{10}N_2O_3$	146.15	parenteral nutrition, treatment of mental disorders and alcoholism	
Glycine	[*56-40-6*]	$C_2H_5NO_2$	75.07	parenteral nutrition, antacid in conjunction with calcium carbonate	Cicatrex, Felacomp, Gastripan-K, Mirogastrin
aluminum, hydrate	[*13682-92-3*]	$C_2H_6NO_4Al$ $(+xH_2O)$	135.1	antacid	Acidrine, Al-Glycin
L-Histidine	[*71-00-1*]	$C_6H_9N_3O_2$	155.16	parenteral nutrition, essential amino acid for infants	
acetate		$C_8H_{13}N_3O_4$	215.21		
hydrochloride monohydrate	[*5934-29-2*]	$C_6H_{12}ClN_3O_3$	209.63		Anti-rheuma, Rollkur-Ankermann, Laristine, Plexamine
L-Isoleucine	[*73-32-5*]	$C_6H_{13}NO_2$	131.18	parenteral nutrition, treatment of hepatic coma, dietary supplement	
L-Leucine	[*61-90-5*]	$C_6H_{13}NO_2$	131.18	parenteral nutrition, treatment of hepatic coma, dietary supplement	numerous combinations
D,L-Lysine	[*70-54-2*]	$C_6H_{14}N_2O_2$	146.19	formation of salts with acidic drugs (to enhance solubility)	
monohydrochloride	[*70-53-1*]	$C_6H_{15}ClN_2O_2$	182.65	geriatric	Jestrosemin
acetylsalicylate	[*34220-70-7*]	$C_{15}H_{22}N_2O_6$	326.34	soluble form of acetylsalicylic acid (aspirin) for injection	Aspisol, Delgesic
L-Lysine	[*56-87-1*]	$C_6H_{14}N_2O_2$	146.19	parenteral nutrition, dietary supplement, prophylaxis of	numerous combinations
acetate	[*57282-49-2*]	$C_8H_{18}N_2O_4$	206.24	herpes simplex infection (?)	
L-aspartate	[*27348-32-9*]	$C_{10}H_{11}N_3O_6$	279.30	dietary supplement	
L-glutamate	[*5408-52-6*]	$C_{11}H_{23}N_3O_6$	293.32	dietary supplement	
L-malate	[*71555-10-7*]	$C_{10}H_{20}N_2O_7$	280.28	dietary supplement	
monohydrate	[*39665-12-8*]	$C_6H_{16}N_2O_3$	164.21	dietary supplement	
monohydrochloride	[*657-27-2*]	$C_6H_{15}ClN_2O_2$	182.65	treatment of hypochloremia, alkaloses	Aktivanad, Athensa, Omnival, Vivioptal
D,L-Methionine	[*59-51-8*]	$C_5H_{11}NO_2S$	149.21	lipotropic and choleretic agent	numerous combinations
L-Methionine	[*63-68-3*]	$C_5H_{11}NO_2S$	149.21	parenteral nutrition, dietary supplement, lipotropic agent, treatment of paracetamol poisoning	
L-Ornithine					
acetate	[*60259-81-6*]	$C_7H_{16}N_2O_4$	192.22	parenteral nutrition	
L-aspartate	[*3230-94-2*]	$C_9H_{19}N_3O_6$	265.27	treatment of hepatic disorders	Hepa-Merz
monohydrochloride	[*3184-13-2*]	$C_5H_{13}ClN_2O_2$	168.62	parenteral nutrition	Ornitaine, Polilevo
2-oxoglutarate	[*5191-97-9*]	$C_{10}H_{18}N_2O_7$	278.14	treatment of hepatic disorders (hyperammonemia)	Ornicetil
D-Phenylalanine	[*673-06-3*]	$C_9H_{11}NO_2$	165.19	antidepressant	
L-Phenylalanine	[*63-91-2*]	$C_9H_{11}NO_2$	165.19	parenteral nutrition	
L-Proline	[*147-85-3*]	$C_5H_9NO_2$	115.13	parenteral nutrition, dietary supplement, starting material for captopril and enalapril	
L-Pyroglutamic acid	[*98-79-3*]	$C_5H_7NO_3$	129.07	formation of salts with basic drugs	
D,L-Serine	[*302-84-1*]	$C_3H_7NO_3$	105.09	starting material for benserazide	Aktiferrin
L-Serine	[*56-45-1*]	$C_3H_7NO_3$	105.09	parenteral nutrition, dietary supplement	Sulfolitruw
L-Threonine	[*72-19-5*]	$C_4H_9NO_3$	119.12	parenteral nutrition, dietary supplement	
L-Tryptophan	[*73-22-3*]	$C_{11}H_{12}N_2O_2$	204.23	parenteral nutrition, antidepressant, sleep inducer, dietary supplement	Optimax, Kalma, Pacitron
L-Tyrosine	[*60-18-4*]	$C_9H_{11}NO_3$	181.19	parenteral nutrition, dietary supplement	
L-Valine	[*72-18-4*]	$C_5H_{11}NO_2$	117.15	parenteral nutrition, dietary supplement, treatment of hepatic coma	

Methiosulfonium chloride is used for its protective effect on the liver and gastrointestinal mucosa, whereas the iodide finds use for rheumatic disorders. The compounds are made by heating L-methionine with methyl chloride or methyl iodide [288].

Trade names: Chloride: Ardesyl (Beytout, France), withdrawn from the market; Cabagin (Kowa, Japan). Iodide: Lobarthrose (Opodex, France), withdrawn from the market.

Oxitriptan [*4350-09-8*], (*S*)-5-hydroxytryptophan, $C_{11}H_{12}N_2O_3$, M_r 220, *mp* 273 °C (decomp.), $[\alpha]_D^{22}$ −32.5° (*c* = 1 in H_2O), $[\alpha]_D^{22}$ + 16.0° (*c* = 1 in 4 M HCl).

This intermediate in mammalian biosynthesis of serotonin is used as an antidepressant. It is produced either by total synthesis (analogous to L-tryptophan via the 5-benzyloxy derivative) [289–291] or by fermentation with *Chromobacterium violaceum* [292].

Trade names: Levothym (Promonta Lundbeck, Germany), Lévotonine (Panpharma, France), Oxyfan (Coli, Italy), Tript-OH (Sigma-Tai, Italy).

D-Penicillamine [*52-67-5*], D-3-mercaptovaline, D-β,β-dimethylcysteine, $C_5H_{11}NO_2S$, M_r 149.21, *mp* 198.5 °C, $[\alpha]_D^{25}$ −63° (*c* = 0.1, pyridine). Hydrochloride [*2219-30-9*], $C_5H_{12}ClNO_2S$, M_r 185.7, *mp* 177.5 °C (decomp.) $[\alpha]_D^{25}$ −63° (*c* = 1 in 1 M NaOH).

D-Penicillamine is a chelating agent that aids the elimination of toxic metal ions, e.g., copper in Wilson's disease. It is used, as an alternative to gold preparations, in the treatment of severe rheumatoid arthritis. It is useful in treating cystinuria because it reacts with cystine to form cysteine-penicillamine disulfide, which is much more soluble than cystine.

D-Penicillamine is produced by hydrolysis of benzylpenicillin (→ Antibiotics, Chap. 4) via its Hg(II) complex [293] or by total synthesis. In the synthesis, isobutyraldehyde, sulfur, and ammonia are condensed to 5,5-dimethyl-2-isopropyl-Δ^3-thiazoline, which, on reaction with hydrogen cyanide, gives 5,5-dimethyl-2-isopropyl-thiazolidine-4-carbonitrile. Hydrolysis with boiling hydrochloric acid yields D,L-penicillamine hydrochloride. Cyclization with acetone and formylation leads to D,L-3-formyl-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, which can be resolved with (−)-phenylpropanolamine via the diastereomeric salts. Hydrolysis with hydrochloric acid leads to D-penicillamine hydrochloride [294].

Trade names: Cuprimine (Merck Sharp & Dohme, USA), Depen (Carter-Wallace, USA), Distamine (Dista, UK), Metalcaptase (Heyl, Germany), Trolovol (ASTA Medica AWD, Germany), Trisorcin (Merdele, Germany), Trolovol (Bayer, France), Pendramine (ASTA Medica, UK), Pemine (Lilly, Italy).

5.4. Cosmetics

Amino acids are a major component of the "natural moisturizing factor" (NMF) that protects the skin surface from dryness, brittleness, and a deleterious environment [295]. The epidermis of the skin contains about 15 % water, which, in the presence of amino acids, principally serine, citrulline, and alanine, forms a stable water-in-oil emulsion with the skin lipids in the form of a thin layer. The amino acids simultaneously stabilize the pH of the skin (the acidic layer), and can be absorbed into the skin and hair. Because of these properties, amino acids [296, 297], protein hydrolysates [298], and proteins [296] are widely utilized in skin and hair cosmetics, e.g., in mild skin creams, skin cleansing lotions, and hair shampoos. It has been claimed that 60 % of hair strength is accomplished by three amino acids, i.e., histidine, lysine, and tyrosine, and supplementing these in hair shampoos can reduce loss of hair strength and improve shine [299]. Methionine is absorbed into the scalp and absorbed by the hair fibers as cysteine, which

is responsible for the cross-linking of keratin [300]. A report published in 2004 claims that amino acids comprise the fastest growing area of new ingredients in the moisturizers and humectants market [301]. Amino acids manufactured by fermentation rather than extracted from animal protein have been increasingly promoted as being more "natural", and this has helped to increase the market for these products.

The sodium salts of the reaction products of fatty acids with amino acids, such as glutamic acid [302–305], or short-chain peptides (protein hydrolysates) [306, 307] are surfactants. They are effective, skin-compatible cleaners and emulsifiers, which are used in shampoos, shower gels, baby baths, medicinal skin cleansers, cold-wave preparations, etc. [303, 308, 309]. Arginine has been used as the cation in soaps to improve the foam volume, and the free amino acid has been used in conditioners to improve sensory properties [310]. The sulfur-containing amino acids exhibit a special normalizing effect on skin metabolism, e.g., in cases of excess skin lipid production (seborrhea), dandruff, or acne. Substances utilized for this purpose include derivatives of cysteine (e.g., *S*-carboxymethylcysteine), homocysteine (2-amino-4-mercaptobutyric acid), and methionine [311]. Amino acids are also used in hair lotions, where they are reported to have a nutritive effect [312]. Cysteine, which acts as a reducing agent, is gaining importance, especially in Japan, as a substitute for thioglycolic acid in permanent wave preparations that are less damaging to hair [313]. Use of aluminum, tin, and zirconium complexes of amino acids, especially glycine, as deodorants [314] and antiperspirants [314, 315] has been reported.

The use of peptides as mimics of human protein fragments in cosmetics has been developed since 2000. One such product is Matrixyl (Sederma), a pentapeptide (Palmitoyl-Lys-Thr-Thr-Lys-Ser), which is a mimic of a precollagen fragment [316]. Matrixyl is applied in antiwrinkle creams. Another example is the dipeptide *N*-acetyl-Tyr-Arg-cetyl ester, registered as Calmosensine (Sederma), which stimulates endorphin precursor release in skin cells and acts as a mild analgesic [317].

5.5. Agrochemicals

An increasing number of pesticides [318] are derivatives of natural or nonnatural amino acids. Important amino acids like Glyphosate or Glufosinate are major products in the agrochemical market. The synthesis of the active ingredient may start with an amino acid, but very often the amino acid moiety is formed during the chemical synthesis.

5.5.1. Herbicides (→ Weed Control)

All pesticide segments (i.e., herbicides, fungicides, insecticides) contain compounds with amino acid substructures, but the major application of pesticidal amino acids is in the herbicide area [319].

Glyphosate [*1071-83-6*] [320], Roundup, $C_3H_8NO_5P$, M_r 169.1, *mp* 200 °C, is the isopropylamine salt of a phosphorus containing glycine derivative with a hybrid structure [321].

Its mode of action is unique; it inhibits different enzyme systems that leads to the blocking of different amino acid biosyntheses. The substance is used as a nonselective contact herbicide to control deep rooted weeds. The sales [322] in 1997 grew to about $\$2180 \times 10^6$ and reaching this figure it is the worlds top selling pesticide. The growth rates were double digits in the 1990s (17 %) and for 2002 an annual production of 180 000 t was estimated. Additional driving impact on the sales of glyphosate has been achieved by the introduction of glyphosate resistant crops (1996: soy beans, 1997: canola and cotton, 1998: maize) and the consequent distribution of genetically engineered seeds in combination with this herbicide.

The classical synthesis starts with iminodiacetic acid, phosphorous trichloride and formaldehyde, but also sequences using glycine and dimethyl phosphate have been applied. There are no confirmed reports of resistance. The expiration of the original patent and the advent of generic producers guarantee an increase of production of the substance becoming a bulk chemical.

Sulfosate [*81591-81-3*] [323], Touchdown, $C_6H_{16}NO_5PS$, M_r 245.2, is the trimethylsulfonium salt of Glyphosate also applied as a nonselective herbicide that was introduced in 1989. As in the case of Glyphosate, sales are growing well.

Glufosinate [324], Basta, Phosphinothricine [*53369-07-6*], $C_5H_{12}NO_4P$, M_r 181.1, *mp* 215 °C (for the ammonium salt). This phosphorous analogue of glutamic acid was introduced in 1984 as a nonselective herbicide in the speciality market, but meanwhile also resistant crops have been developed, which are distributed in combination with the herbicide (Liberty Link). In 1997 the sales were at $170 × 10^6.

The contact herbicide inhibits the plant specific enzyme glutamine synthetase. The chemical synthesis requires acrolein, hydrocyanic acid and methyl phosphinous ester, resulting in a racemic product [325]. As the L-enantiomer is 40 times more active than the D-compound, many asymmetric synthetic routes are under investigation.

Bialofos [*35597-43-4*] [326], Bilanafos, $C_{11}H_{22}N_3O_6P$, M_r 323.3, *mp* 160 °C (decomp.), is a natural occurring tripeptide of the sequence L-phosphinothricine-L-alanine-L-alanine isolated from *Streptomyces viridochromogenes, Streptomyces hygroscopicus* and others. The compound was launched as a nonselective contact herbicide in 1984. It has the same mode of action as Glufosinate, but has much lower sales.

Herbicides Based on 2-Methylvaline. In 1985, the first member of a new and very important class of selective herbicides based on 2-methylvaline was introduced. These imidazolinone herbicides are acetolactate synthase (ALS) inhibitors [327] meaning that the synthesis of branched amino acids is blocked [328].

The synthesis of the racemic active ingredients starts from methyl isopropyl ketone which is converted to 2-methylvaline and finally cyclized to an imidazolinone with an *ortho*-carboxy substituted aromatic or heteroaromatic ring system. The sales of the imidazolinone herbicides grew with 6.8 % per annum from 1992 to 1997. The sales for Imazethapyr, the star product against mono- and dicotyl weeds in soya were about $540 × 10^6 in 1997.

Imazaquin [*81335-37-7*], 2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)-3-quinoline carboxylic acid, Scepter, $C_{17}H_{17}N_3O_3$, M_r 311.3, *mp* 219–224 °C, was launched in 1984.

Imazapyr [*81334-34-1*], 2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)-nicotinic acid, Arsenal, $C_{13}H_{15}N_3O_3$, M_r 261.3, *mp* 169–173 °C, was launched in 1985.

Imazamethabenz [*81405-85-8*], 2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)-5-methylbenzoic acid methyl ester, Assert, $C_{15}H_{18}N_2O_3$, M_r 274.3, *mp* 113–153 °C (of methyl ester), was launched in 1986.

Imazethapyr [*81335-77-5*], 5-ethyl-2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)nicotinic acid, Pursuit, $C_{15}H_{19}N_3O_3$, M_r 289.3, *mp* 169–173 °C, was launched in 1987.

Imazapic [*104098-48-8*], 5-methyl-2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)-nicotinic acid, Cadre, $C_{14}H_{17}N_3O_3$,

M_r 275.3, *mp* 204–206 °C, was launched in 1997.

Imazamox [*114311-32-9*], 2-(4-isopropyl-4-methyl-5-oxo-4,5-dihydro-1*H*-imidazol-2-yl)-5-methoxymethylnicotinic acid, Raptor, $C_{15}H_{19}N_3O_4$, M_r 305.3, *mp*, was launched in 1997.

Herbicides derived from Acylphenyl Amino Acids. Acylphenyl amino acids are a group of herbicides with decreasing importance. The development of enantiomerically pure compounds are new concepts for improving the substance performance.

Benzoylprop [*22212-56-2*] [329], Suffix, $C_{16}H_{13}C_{12}NO_3$ (for ethyl ester), has an alanine subunit, which is formed by reacting 3,4-dichloroaniline with racemic ethyl 2-chloropropionate and benzoyl chloride. This herbicide is mainly used in wheat. The racemic active ingredient and the analogue with an 3-chloro-2-fluoroaniline aromatic are more and more replaced by the D-alanine derivative (racemic switch).

Flamprop-M [*63782-90-1*] [330], Mataven L, Suffix BW, $C_{19}H_{19}ClFNO_3$, M_r 363.8, *mp* 72.5–74.5 °C (data for isopropyl ester), is synthesized from 3-chloro-4-fluoroaniline, benzoyl chloride and methyl *S*-2-chloro propionate. This compound is used as selective grass herbicide in wheat and barley.

Amino Acids in Protox Herbicides. Inhibitors of the protoporphyrinogene oxidase [331], also known as Protox, are important herbicides blocking the biosynthesis of chlorophyll in plants. Phenyl substituted heterocycles have a strong impact on that enzyme [332]. These herbicides can contain amino acids in two ways. On the one side, amino acids like proline, 4-oxaproline [333] or pipecolinic acid [334] could be part of the heterocycle forming a hydantoin, on the other side amino acids like alanine can form the substituent at 5-position of the aromatic system. The preemergence activity and selectivity is increased using the R-enantiomer instead of the racemic alanine.

Herbicides Based on Glycine. Two herbicides based on a glycine residue are the chloroacetanilide herbicide Diethatyl [*38725-95-0*], Antor, $C_{14}H_{18}ClNO_3$ M_r 283.75, produced by Hercules Agrochemicals [318]

and the triazine herbicide Eglinazine [*68228-19-3*], $C_7H_{10}ClN_5O_2$, M_r 231.64, introduced by Nitrokémia Ipartelepek [318]

5.5.2. Fungicides (→ Fungicides, Agricultural)

Valinamide Fungicides. A lot of acylvaline anilides are claimed to be active against a broad spectrum of fungi, but especially the control of *Plasmopara* and *Phytophthora* [335] is pointed out. The literature indicates [336] that the *S*-compound is the more active enantiomer. This

group of compounds may be divided into valine derivatives and nonvaline derivatives. The valine is usually acylated to form an urethane or a maleimide. The carboxylic group is condensed with a substituted aniline, an alkyl benzylamine or an alkyl homobenzylamine [337, 338].

Two valinamide fungicides have been introduced into the market.

Iprovalicarb [*140923-17-7*], Melody, $C_{18}H_{28}N_2O_3$, M_r 320.43, has been introduced by Bayer CropScience for the prevention of downy mildew and *Phomopsis viticola* in vines [339]. The valine moiety is in the L-form, but the stereochemistry of the second asymmetric center is not defined.

Benthiavalicarb [*413615-35-7*], $C_{15}H_{18}FN_3O_3S$, M_r 339.38, has been developed by Kumiai Chemicals Industry for treatment of tomatoes and potato late blight [340].

Anilide Fungicides. A number of anilide fungicides with a market volume of approx. $610 × 10^6 in 1997 have been established since the 1990s. Three amino acid derivatives are sold as fungicides with systemic activity.

Metalaxyl [*57837-19-1*] [341], Ridomil, $C_{15}H_{21}NO_4$, M_r 279.3, *mp* 71.8–72.3 °C (data for isopropyl ester). This most important fungicide of its class is synthesized by condensation of 2,6-dimethylaniline with methoxyacetyl chloride and subsequent coupling with racemic methyl 2-chloropropionate.

This fungicide is mainly used for the seed treatment business, in wine and in vegetables. The compound is sold as a stand-alone product or in a variety of mixtures with other fungicides. It was introduced in the market in 1978. The (*R*)-isomer, based on D-alanine, is known as Metalaxyl-M [*70630-17-0*] or Ridomil Gold, and was introduced by Syngenta in the USA in 1996.

Furalaxyl [*57646-30-7*], Fongarid, $C_{17}H_{19}NO_4$, M_r 301.3, *mp* 70 and 84 °C (dimorphic) (data for isopropyl ester). Furalaxyl is a condensation product of furan-2-carboxylic acid and 2,6-dimethylaniline which is subsequently coupled with methyl 2-chloropropionate. The compound was introduced in 1984.

Benalaxyl [*71626-11-4*] [342], Galben, $C_{20}H_{23}NO_3$, M_r 325.4, *mp* 78–80 °C. In the commercial synthesis again 2,6-dimethylaniline is coupled with phenylacetyl chloride and subsequently methyl 2-bromopropionate. The single enantiomer product Benalaxyl-M [*98243-83-5*], based on D-alanine, has also been registered.

Hydantoins. Some amino acids being marketed as fungicides are sold as their hydantoins. One established product is iprodione.

Iprodione [*36734-19-7*], Rovral, $C_{13}H_{13}Cl_2N_3O_3$, M_r 330.2, *mp* 134 °C. The synthesis uses 3,5-dichloroaniline which is coupled with glycine and phosgene. The urea substructure is formed by reaction with isopropylamine and phosgene. Many fungicide mixtures with Iprodione are on the market.

Perfuazoate [*101903-30-4*], Healthied, $C_{18}H_{23}N_3O_4$, M_r 345.4. This rice fungicide has been introduced by Showa Denko for the treatment of rice seedlings in Japan [318]. It is based on a racemic homoalanine pentenyl ester backbone.

5.5.3. Insecticides (→ Insect Control)

Only a few amino acid based insecticides are distributed in the market.

tau-Fluvalinate [*102851-06-9*] [343], Klartan, Mavrik, $C_{26}H_{22}ClF_3N_2O_3$, M_r 502.9, *bp* 164 °C (9.33 Pa) is the most important compound. This substance, preferably used in cotton fields, but also in corn, rape tomatoes and vegetables, is a pyrethroid with contact and stomach action. The market of that class had a volume of $1530 × 10^6 in 1997. The chemical synthesis starts with 3,4-dichlorotrifluoromethylbenzene and D-valine. The carboxylic acid is esterified with the cyanohydrin of 3-phenoxybenzaldehyde. The compound is marketed with the defined stereochemistry at the valine moiety, but the cyanohydrin subunit is a *R/S* mixture.

Imiprothrin, Pralle [*72693-72-5*], $C_{17}H_{22}N_2O_4$, M_r 318.4, has been introduced by Sumitomo as a household insecticide against cockroaches and other crawling insects, and is a pyrethroid based on glycine hydantoin. It is sold as a mixture of *cis*- and *trans*-isomers [318]. The long synthetic pathway leads to the vinyl substituted cyclopropane carboxylate, which forms an ester with 3-hydroxymethyl hydantoin. The resulting substance is *N*-alkylated with 3-bromopropyne.

5.5.4. Plant Growth Regulators (→ Plant Growth Regulators)

Two compounds with amino acid structure are highlighted because of their direct chemical relationship to Glyphosate.

Glyphosine [*2439-99-8*] [344], Polaris, $C_4H_{11}NO_8P_2$ was introduced in 1973 and is preferably used in sugar beets. The synthesis starting with glycine uses two equivalents of formaldehyde and of phosphorous trichloride under oxidative conditions.

A second derivative of Glyphosate is a cyclic phosphaoxazole being formed from Glyphosate and formaldehyde. This compound is claimed to control the growth of some grasses without discoloration or phytotoxicity.

Aviglycine [*49669-74-1*], aminoethoxyvinylglycine, ReTain, $C_6H_{12}N_2O_3$, M_r 160.2, is produced by *Streptomyces* spp. and was isolated and purified by Abbott. It is marketed by Valent Biosciences for control of fruit ripening as it inhibits the production of endogenous ethylene [318].

5.6. Industrial Uses

Polyfunctional compounds, such as amino acids and their derivatives, have been applied in a

wide variety of industrial areas. This is particularly because of their physicochemical properties, such as high thermal stability, low volatility, amphoterism, buffering capacity, and the ability to form complexes. However, properties of amino acids such as environmental acceptability and low toxicity, are becoming increasingly important. A few of the recorded uses have been listed below, and include acylamino acid monomers for epoxy resins [345]; amino acid dispersing agents for pigments in coloring polyester fibers [346]; *N*-acylamino acid dispersants for polyurethanes in water [347]; amino acid setting retarders for cement [348]; zinc salts of *N*-acyl-derivatives of basic amino acids and *N*-acylamino acids for the thermal stabilization of PVC [349]; polyglutamic acid esters and polyaspartic acid esters coatings for natural and synthetic leather [350]; amino acid hardening agents for methacrylate resins [351]; *N*-acylamino acid, amino acid ester, and amino acid amide gel-forming agents for oils [352]; basic amino acid vulcanization accelerators for natural rubber [353]; amino acid [354] and *N*-acylamino acid [355] corrosion inhibitors for metals; amino acids to stabilize the latent image of photographic emulsions [356]; and amino acid brighteners in galvanic baths [357, 358].

6. Chemical Analysis

Amino acids do not have defined melting points but decompose over a broad range between 250 and 300 °C. Therefore, they must be transformed into derivatives before melting points are useful for identification. Phenylisothiocyanate is used to yield the phenylthiohydantoin amino acid (PTH amino acid) [8], or 2,4-dinitrofluorobenzene (Sanger's reagent) is used to yield the dinitrophenyl amino acid [8].

Spectroscopic methods for the identification of amino acids include infrared [359], Raman, ^{1}H-NMR, and ^{13}C-NMR spectroscopy [360] of free amino acids or PTH derivatives and mass spectrometry of PTH derivatives [361]. Ultraviolet spectroscopy is important only for aromatic amino acids. The different methods for qualitative and quantitative analysis of amino acids, particularly of mixtures from protein hydrolysis and biological fluids, have been reviewed [362]. Separation methods are described in [363].

Various *staining methods* may be used for the qualitative identification of α-amino acids [364]. Some of these dye-forming reactions are suitable for quantitative analysis within the validity range of the Lambert–Beer law. By far the most important is the reaction with ninhydrin, which yields a red-violet to blue-violet dye ($\lambda_{max} = 570$ nm).

The imino acids proline and hydroxyproline form a structurally different dye, with an absorption maximum at 440 nm.

Fluorescent reagents also have been used successfully for quantitative analysis. The amino acid is converted into a strongly fluorescent derivative, which increases the sensitivity by orders of magnitude. Typical fluorescent reagents are *o*-phthalaldehyde–2-mercaptoethanol [365], 1-dimethylaminonaphthalene-5-sulfonyl chloride (dansyl chloride) [366], and 4-phenylspiro [furan-2(3*H*)-1′-phthalan]-3,3′-dione (fluorescamine) [367].

The *separation* of amino acid mixtures is possible by electrophoresis or chromatography. The latter is especially useful, techniques including paper, thin layer, ion-exchange, high-pressure liquid, and gas chromatography. The different techniques have been reviewed and compared in [368]. Paper chromatography is generally carried out in two dimensions. A number of eluents are available for this purpose. Quite often the amino acid is converted to its dinitrophenyl derivative.

More common than paper chromatography is *thin layer chromatography* (TLC) of either the free amino acids [369] or their PTH derivatives [370]. Silica gel, aluminum oxide, cellulose powder, or polyacrylamide may be used as carrier, but silica is preferred. An indicator reagent, most often ninhydrin, is used for detection [371]. For detection of very small quantities the amino

acids separated on an TLC plate can be converted to the fluorescamine derivatives [372]. The detection limit is 10 pmol. The time required for the analysis of dinitrophenyl amino acids can be reduced by using high-pressure thin layer chromatography [373]. TLC is often specified as an analytical test to show the levels of foreign amino acids in a sample, particularly when the amino acid is from natural sources.

Ion-exchange chromatography [374, 375] on organic resins (Dowex, Amberlite, etc.) has proven to be the most exact and reliable method for the separation and quantitative analysis of amino acids. Before the automatic analysis technique was introduced [376], complete analysis of an amino acid mixture required 24 h. Today 2 h is the rule. Sodium citrate or lithium citrate buffer solutions are the eluents. The eluate is reacted with ninhydrin [374, 377] or *o*-phthalaldehyde [378]. With ninhydrin, 1–20 nmol amino acid can be measured with an accuracy of $\pm$ 1–5 %. The detection limit with *o*-phthalaldehyde is in the picomole range. Ion-pair chromatography on a porous graphitic carbon stationary phase has also been applied. Detection is by evaporative light scattering, or by electrospray mass spectrometry [379].

Ion-exchange chromatography is the method of choice for analyzing amino acids in feeds, foodstuffs, and biologic fluids [380]. In general, analysis is preceded by a hydrolysis, which degrades the proteins and peptides to their component amino acids. However, acidic hydrolysis can destroy Cys, Met, and Trp residues, and special techniques may be necessary to analyze for these amino acids. Figure 10 shows a sample aminogram of broiler feed.

Utilization of *high-pressure liquid chromatography* (HPLC) allows a further reduction in analysis time. Originally, the amino acids were converted to derivatives, e.g., to dansyl amino acids [381], PTH amino acids [382], or dinitrophenyl derivatives [383], before analysis. Reversed phases are the preferred stationary phases. Ninhydrin, *o*-phthalaldehyde–mercaptoethanol [384], or fluorescamine [385] are the usual reagents for detection. An HPLC method with direct UV detection has also been described [386] for analysis of infusion solutions. Modern automated amino acid analyzers are now available, that use quaternary gradient elution to separate all the common amino acids efficiently without prior derivatization. These machines generally incorporate postcolumn visualization with ninhydrin and photometric quantification. Today this method rivals ion-exchange chromatography as the preferred analytical method.

Gas chromatographic methods [387] are useful for the analysis of complex amino acid mixtures. However, the amino acids must be converted into volatile derivatives, e.g., PTH amino acids [388], methyl esters of *N*-trifluoroacetylamino acids [389], *n*-butyl esters of *N*-trifluoroacetylamino acids [390], *N*-trimethylsilylamino acids [391], or *N,O*-bis-trimethylsilylamino acids [392]. Gas chromatography coupled with electron-capture negative-ionization mass spectrometry (GC–ECNI–MS) has been used to determine amino acids at the femtomole scale, using ^{2}H or ^{13}C labeled amino acids as reference standards [393].

Electrophoresis [394], which employs the differing rates of migration in an electric field, is becoming more important [395]. The technique is already well-established for protein analysis, and has been coupled with electrospray ionization mass spectrometry (CE–ESI–MS) to determine underivatized amino acids at micromolar level [396]. Capillary isotachophoresis is a new high-resolution electrophoresis technique for amino acids.

The chromatographic separation of amino acid enantiomers is the subject of intensive investigation. Separation is currently possible by gas chromatography [397] and high-pressure liquid chromatography [398], using optically active phases or chiral solvents [399]. A wide range of chiral stationary phases is now available for analytical or preparative separations. Another method is to use a chiral precolumn derivatizing agent. Marfey's reagent (1-fluoro-2,4-dinitrophenyl-5-L-alanine amide) has been successfully applied to separate complex mixtures of amino acids into their separate enantiomers, and is effective at the nanomolar scale [400, 401]. Marfey's reagent forms diastereomeric salt pairs with the amino acids, that are particularly well separated by HPLC.

The *microbiological analysis* of amino acids is based on the fact that several L-amino acids are essential for certain bacteria strains. The growth of the bacteria cultures under standard conditions can be quantitatively evaluated (acidime-

Figure 10. Amino acid chromatogram of a broiler feed
Internal standard: norleucine. Solid curve: UV detection at $\lambda = 570$ nm. Dotted curve: UV detection at $\lambda = 440$ nm for Pro (and Hyp).

try or turbidimetry) and related to the amino acid concentration. Lactic acid bacteria [402] (Lactobacteriaceae) can be used to analyze 19 L-amino acids. Typical test microbes include *Leuconostoc mesenteroides* (ATCC 8042), *Lactobacillus arabinosus 17–5* (ATCC 8014), and *Streptococcus faecalis R* (ATCC 9790, 8043). The conventional microbiological methods are quite complicated but can be simplified by automation [403].

A series of L- or D-amino acids can be analyzed by *enzymatic methods.* L-Amino acids, or the enantiomeric purity of D-amino acids, can be determined with bacteria decarboxylases by measurement of CO_2 formed. D-Amino acids, or the enantiomeric purity of L-amino acids, can be determined with kidney D-amino acid oxidases by measurement of the O_2 consumption. Enzymes that react only with a single amino acid allow determination of that amino acid, e.g., arginine using liver arginase. An improved enzymatic method consists of the use of enzyme electrodes that contain the enzymes [404], or microorganisms having a special enzyme in a fixed form. Enzyme electrodes, however, are relatively unstable [405].

The *quantitative determination of crystallized amino acids* is carried out by acidimetric titration in nonaqueous medium [406, 407]. Glacial acetic acid is a suitable solvent. Formic acid may be added to improve solubility. The titrant is perchloric acid. Formol titration by the method of Sörensen can be used for aqueous solutions but is less accurate.

Standards of purity for individual L- and D,L-amino acids that are used in drugs or as food additives are published in pharmacopeias [406, 408] and food codices [409].

7. Economic Significance

The 2005 world market for amino acids is estimated at more than 3.3×10^6 t/a (Table 19). The "big three" amino acids, sodium L-glutamate, D,L-methionine, and L-lysine · HCl, account for approximately 95 % of the volume (Table 20). The other amino acids play only a small role. The dominant amino acid, sodium glutamate, is used almost exclusively as a taste enhancer. D,L-Methionine and L-lysine · HCl are used almost exclusively to improve the nutritive value of animal feeds. L-Threonine is also used mainly in animal feeds. L-Aspartic acid and L-phenylalanine are used principally for the manufacture of the intense sweetener aspartame. The other amino acids have diversified applications. With the exception of glycine, they are more expensive than the big three amino acids. In terms of

volume, feed additives used about 1 500 000 t of amino acids, pharmaceuticals 17 000 t and sweeteners around 17 000 t (2005) [410]. Table 21 shows the market value for amino acids in 2004 broken down by field of use [52]. The total value of the global amino acids market in 2004 was estimated at \$ 4.5×10^9 [52].

Table 19. Amino acid production, 2005

Amino acid	Quantity, t/a [410–413]
L-Alanine	1500
L-Arginine *	3000
L-Asparagine	200
L-Aspartic acid	15 000
L-Cysteine *	7000
L-Glutamic acid *	1 690 000
L-Glutamine	2000
Glycine	16 000
L-Histidine	300

L-Glutamic acid (Na)	51
D,L-Methionine	18
L-Lysine (HCl)	26
Other amino acids	5

Table 21. Market value by field of use, 2004

Use	Value, %
Animal nutrition	56
Human nutrition	32
Specialty *	12

* Pharmaceuticals, cosmetics, agrochemicals, and industrial uses.

The main manufacturers of amino acids are located in Japan (e.g., Ajinomoto, Kyowa Hakko, Tanabe) and in Europe (Degussa, Wacker, Amino, Flamma). Recently there has been an increasing trend towards production in China, with established manufacturers setting up plants there.

8. Toxicology

Excess amino acids are rapidly disposed of by increased metabolic degradation. Should the amino acid dose be suddenly increased, e.g., by extremely high protein consumption, within about two days the liver adaptively increases the levels of amino acid-catabolizing enzymes — transaminases, enzymes of the urea cycle, cystathionase, tryptophan pyrrolase, etc. The excess amino acids are to a large extent used to provide energy. The nitrogen is eliminated as urea. A smaller portion is used in protein synthesis, mainly liver protein and plasma albumin.

When too little protein or no protein is consumed or when the component amino acids are imbalanced, alteration of the ribosome profile occurs in the liver, and ribonucleic acids are catabolized. The manifestation of chronic protein deficiency is known as marasmus (slight deficiency) and kwashiorkor (extreme deficiency). Protein deficiency is usually coupled with calorie deficiency (protein–calorie malnutrition). This manifests itself on the biochemical level as a negative nitrogen balance, indicating a reduction in protein inventory. Initially, the labile enzyme and plasma proteins are consumed, the greatest losses occurring first in the liver, then in the musculature. Brain, heart, and kidneys suffer only minimal protein loss. Symptoms of protein synthesis disorders include disturbances in wound healing and bone growth, lowered resistance to infection and stress, loss of fertility and appetite, and anorexia. The urinary excretion of 3-methylhistidine is a common indicator of the catabolism of muscle protein.

The total absence of an essential amino acid in the diet is more serious than protein deficiency. In this case the proteins or amino acids in the diet are totally worthless because protein synthesis can occur only by degradation of body protein. A general interruption of the protein synthesis results. This manifests itself rapidly as a drop in enzyme activity and an impoverishment of the plasma proteins. Noticeable symptoms are loss of appetite and weight, alteration of cornea and lens, anatomic organ alterations, and an increased rate of mortality. In addition

there appear specific deficiency symptoms characteristic of the missing amino acid or acids.

The metabolic disturbances brought about by gross divergences from the optimal amino acid pattern have three different causes [414, 415]: imbalance, antagonism, and toxicity.

Amino acid imbalance manifests as an appearance of deficiency symptoms for the first limiting amino acid when the other amino acids are consumed in great excess. The symptoms of imbalance are eliminated by administration of the first limiting amino acid in sufficient quantities. The main symptom is a severe reduction of food or feed assimilation and depression of growth. The depression of growth in rats has been investigated intensively by adding individual L- and D,L-amino acids to basal diets of various protein levels [416, 417].

*Amino acid antagonism*is caused by competition for common transport systems. An example is antagonism of the branched-chain amino acids isoleucine, leucine, and valine. The symptoms are reversible. In a study with young rats, addition of 5 % L-leucine to a low-protein diet (9 % casein) reduced the plasma levels of isoleucine and valine, depressed growth, and reduced feed consumption [418]. These effects were eliminated after a latent period of three days by small doses of L-isoleucine (0.16 %) and L-valine (0.15 %).

Amino acid toxicity occurs when very large quantities of one or more amino acids are consumed and is characterized by total failure of the adaptive mechanisms. The toxic level has been studied by adding increasing quantities of individual amino acids to a protein basal diet [415]. The toxicity of individual amino acids depends on the total protein consumption. Imbalance, antagonism, and toxicity are less pronounced when overall protein consumption is sufficient but become more severe at lower levels of protein consumption. The consumption of toxic amounts of amino acids increases their concentration in the plasma and brain. Because of the blood–brain barrier, however, the increase in the brain is not as great [419]. Failure of the adaptation mechanisms during consumption of large excess of an amino acid can lead to accumulation of the amino acids or certain metabolites in the organism, leading directly or indirectly (e.g., by influencing hormone secretion) to anatomic or functional damage.

The toxicity of amino acids has been reviewed [415, 418]. The acute toxicities of most L-amino acids and some derivatives have been determined [420–422]. The toxicology of D-amino acids is discussed in review articles [415] and other publications [421, 422]. There is no evidence to date that the D-enantiomers of the α-amino acids found in proteins exhibit specific toxic effects. Their LD_{50} values are generally higher than those of the L-amino acids.

1. Aminophenols

Aminophenols and their derivatives are of steadily increasing commercial importance, both in their own right and as intermediates in the chemical and dye industries. They are amphoteric and can behave either as weak acids or weak bases, but the basic character usually predominates. 2-Aminophenol (**1**) and 4-aminophenol (**2**) are oxidized easily. This is the basis for their main applications, for example, as photographic developers. In contrast, 3-aminophenol (**3**) is fairly stable in air and is not oxidized rapidly.

1 **2** **3**

1.1. Physical Properties

The simple aminophenols exist in three isomeric forms depending on the relative positions of the hydroxyl and amino groups around the benzene ring. At room temperature they are solid crystalline compounds. The commercial-grade compounds are usually impure because of contamination with oxidation products and may take on a yellow-brown or pink-purple hue, the 2- and 4-aminophenols being more susceptible to this phenomenon than the 3-isomer. The solubilities of these compounds in common solvents and their spectral characteristics are given in Tables 1 and 2, respectively [3–12].

Table 1. Solubility ∗ of aminophenols in common solvents

	2-Aminophenol	3-Aminophenol	4-Aminophenol
Acetone	3	3	2
Acetonitrile	3	3	2
Benzene	1	1	0
Chloroform	1	1	0
Diethyl ether	2	2	1
Dimethylsulfoxide	3	3	3
Ethanol	3	3	1
Ethyl acetate	3	3	2
Toluene	1	1	1
Water			
Cold	1	2	1
Hot	2	3	2

∗ 0, insoluble; 1, slightly soluble; 2, soluble; 3, very soluble

2-Aminophenol (**1**) [*95-55-6*], 2-hydroxyaniline, 2-amino-1-hydroxybenzene, C.I. Oxidation Base 17, C.I. 76520, C_6H_7NO, M_r 109.13, forms white orthorhombic bipyramidal needles when crystallized from water or benzene, *mp* 174 °C. The crystals have eight molecules to the elementary cell and a density of 1.328 g/cm^3 (1.29 also quoted) [13–16]. At reduced pressure (1.47 kPa), 2-aminophenol sublimes rapidly at 153 °C without decomposition [17]. Acid – base dissociation constants are pK_1 4.72 (water at 21 °C), 4.66 (1 vol % ethyl

[b] UV spectra: cyclohex. = cyclohexane containing 2 vol % diethyl ether [6–8].
[c] Proton chemical shift spectra over the range of 0 – 15 ppm ($\pm$ 0.1 ppm); TFA, trifluoroacetic acid; DMSO, dimethylsulfoxide. When complex spectra caused by second-order effects or overlapping resonances were encountered the range was recorded [10], [11].

alcohol in water at 25 °C); pK_2 9.66 (water at 15 °C), 9.71 (water at 22 °C) [18], [19]. Salts: hydrochloride [*51-19-4*], needles, *mp* 207 °C; formate, *mp* 120 °C; oxalate, *mp* 167.5 °C (decomp.); acetate, *mp* 150 °C.

3-Aminophenol (**3**) [*591-27-5*], 3-hydroxyaniline, 3-amino-1-hydroxybenzene, C_6H_7NO, M_r 109.13, forms white prisms when crystallized from water or toluene, *mp* 122 – 123 °C. The orthorhombic crystals have a tetramolecular unit and a density of 1.195 g/cm^3 (1.206 and 1.269 also quoted) [14–16]. 3-Aminophenol boils at 164 °C at 1.47 kPa with slight decomposition [17]. Acid – base dissociation constants are: pK_1 4.17 (water at 21 °C), 4.31 (1 vol % aqueous ethyl alcohol at 25 °C); pK_2 9.87 (water at 22 °C) [18]. Salts: hydrochloride [*51-81-0*], prisms, *mp* 229 °C; hydrobromide, prisms, *mp* 224 °C; hydroiodide, prisms, *mp* 209 °C; sulfate [*66671-80-5*], plates or needles, *mp* 152 °C; oxalate, *mp* 275 °C.

4-Aminophenol (**2**) [*123-30-8*], 4-hydroxyaniline, 4-amino-1-hydroxybenzene, C_6H_7NO, M_r 109.13, forms white plates when crystallized from water, *mp* 189 – 190 °C (decomp.). The crystals exist in two forms. The α form (from alcohol, water, or ethyl acetate) is the more stable and has an orthorhombic pyramidal structure containing four molecules per unit cell. It has a density of 1.290 g/cm^3 (1.305 also quoted). The less stable β form (from acetone) exists as acicular crystals that turn into the α form on standing; they are orthorhombic bipyramidal or pyramidal and have a hexamolecular unit [14], [15], [20]. At reduced pressure (40 Pa) 4-aminophenol sublimes at 110 °C with slight decomposition. Boiling points quoted at various pressures are as follows: 284 °C (101.3 kPa), 174 °C (1.47 kPa), 167 °C (1.07 kPa), 150 °C (0.4 kPa), 130.2 °C (0.04 kPa), decomposition usually occurring. Acid – base dissociation constants are: pK_1 5.50 (water at 21 °C), 4.86 (water at 30 °C), 5.48 (1 vol % aqueous ethyl alcohol at 25 °C); pK_2 10.30 (water at 22 °C), 10.60 (water at 30 °C) [18], [21]. Salts: hydrochloride [*51-78-5*], prisms, *mp* 306 °C (decomp.); hydrosulfate [*15658-52-3*], needles, *mp* 272 °C; oxalate, *mp* 183 °C; acetate [*13871-68-6*], *mp* 183 °C; chloroacetate, needles, *mp* 148 °C; trichloroacetate, needles, *mp* 166 °C.

1.2. Chemical Properties

The chemical properties and reactions of the aminophenols are to be found in detail in many standard chemical texts and only a summary is given here [22].

The acidity of the phenols is depressed by the presence of an amino group on the benzene ring; this phenomenon is most pronounced with 4-aminophenol. They also behave as weak bases, giving salts with both mineral and organic acids. The aminophenols are true ampholytes, with no zwitterion structure; hence they exist either as neutral molecules (**4**) or as ammonium cations (**5**) or phenolate anions (**6**), depending on the pH value of the solution.

5 **4** **6**

However, deviations from theoretical curves observed during acid – base titrations have led to postulation of the existence of half-salt complex cations B_2^+, formed by the association of an ammonium cation, B^+, with a neutral molecule, B. This association phenomenon is most apparent with 4-aminophenol but is also displayed by the other isomers [21].

The aminophenols are chemically reactive, undergoing reactions involving both the aromatic amino group and the phenolic hydroxyl moiety, as well as substitution on the benzene ring. Oxidation leads to the formation of highly colored polymeric quinoid structures. 2-Aminophenol undergoes a variety of cyclization reactions.

Alkylation. All of the possible mono-, di-, and trimethylated aminophenols are known. *N*-Monoalkylation occurs when the aminophenol is heated with the appropriate alkyl halide or with an alcohol and Raney nickel; equal or even better results can be achieved by using aldehydes or ketones in place of the alcohol. Specific alkylation of the hydroxyl group to form methoxyanilines (anisidines) or ethoxyanilines (phenetidines) is difficult because of the reactivity of the amino group; mixed alkylated products usually are obtained. 3-Methoxyaniline may be prepared by methylation of 3-aminophenol under alkaline conditions, but it is more usual to protect the amino group and to methylate 3-acetylaminophenol, followed by hydrolysis. The other anisidines and phenetidines are prepared indirectly by reduction of the nitro analog:

Acylation. Acylation of the aminophenol (using acetic anhydride in alkali or pyridine, acetyl chloride and pyridine in toluene, or ketene in ethanol) usually leads to *N*-acylated products. If an excess of reagent is used, however, especially with 2-aminophenol, *O,N*-diacylated products are formed. Aminophenyl carboxylates (*O*-acylated aminophenols) normally are prepared by the reduction of the corresponding nitrophenyl carboxylates, which is of particular importance with the 4-aminophenol derivatives. A migration of the acyl group from the *O* to the *N* position is known to occur for both 2- and 4-aminophenol acylated products. 2-Aminophenyl ethyl carbonate (**7**) rearranges slowly in dilute acid to ethyl 2-hydroxyphenyl carbamate (**8**); the corresponding 4 derivative does not undergo this particular reaction [23].

7 **8**

Diazonium Salt Formation. The aromatic amino group of aminophenols can be converted to the diazonium salt with sodium nitrite in aqueous acid, although difficulties may be encountered when the aminophenol is oxidized easily or of low solubility. Crystalline diazonium salts have been isolated by using the hydrochloride or sulfate of the appropriate aminophenol under anhydrous conditions. Such diazo derivatives find extensive use in the dye [24], [25].

Cyclization Reactions. Owing to the close proximity of the amino and hydroxyl groups in 2-aminophenol, this isomer is particularly susceptible to cyclization and condensation reactions. Oxidation by iron(III) chloride, enzymes, or light or autoxidation on silica thin-layer plates gives 2-aminophenoxazin-3-one (**9**). Further oxidation with iron(III) cyanide or heating with potassium hydroxide in ethanol gives a five-ring structure, triphenoxdioxazine (benzoxazinophenoxazine) (**10**). 2-Aminophenol and its derivatives are useful starting materials for the synthesis of phenoxazones, phenoxazines, benzoxazoles, and thiobenzoxazoles. Most of these condensation reactions involve heating at 200 – 300 °C with a suitable catalyst [22].

9

10

Condensation Reactions. Substituted diphenylamines or diphenyl ethers are obtained from aminophenols and suitable reactants by elimination of ammonia or hydrogen chloride:

Reactions of the Benzene Ring. Both the amino and hydroxyl groups are electron-donating moieties, and many substituted derivatives are known. The controlled interaction of aminophenols with chlorine or bromine in glacial acetic acid can give a variety of mono-, di-, tri-, or tetra-halogenated products. The use of concentrated sulfuric acid or oleum, with or without heat, gives aromatic sulfonic acids. The sulfonic acid group enters the *ortho* or *para* position relative to the hydroxyl group. Further treatment with oleum leads to the formation of disulfonated compounds. The carboxylation of *m*-aminophenol leads to the formation of *p*-aminosalicylic acid.

1.3. Production

Aminophenols are made either by reduction of nitrophenols or by substitution. Reduction is accomplished with iron or with hydrogen in the presence of a catalyst. The last mentioned is the method of choice today for the production of 2- and 4-aminophenol.

1.3.1. Reduction

Iron Reduction [26]. The reduction of nitrophenols with iron turnings takes place in weakly acidic solution or suspension. Before the iron – iron oxide sludge is separated from the solution [27] the product aminophenol must be made water soluble by adding sodium hydroxide. The resulting sodium aminophenolate is very susceptible to oxidation in aqueous solution; various methods are recommended for its purification (see Section 1.3.3). Subsequent to this, the aminophenols are precipitated from acidic solution by neutralization with base and in the absence of air; reducing agents usually must be added during this procedure.

When 2-nitrophenol is reduced with iron, red insoluble color lakes are formed as byproducts that decrease the yield. Therefore, the iron reduction of 2-nitrophenol is of minor industrial importance today.

Catalytic Reduction [28–30]. Catalytic reduction usually takes place in solution, emulsion, or suspension in autoclaves or pressurized vessels; after the catalyst is added, the vessel is pressurized with hydrogen. Water and methanol are the preferred solvents; in water the addition of alkali hydroxide [31–34], alkali carbonate [31], [34], or acid [34], [35] has been recommended. Nickel [36] – preferably Raney nickel [32], [33], [37], [38] – or supported precious metals [31], [39], such as platinum or palladium [34], [40] on activated carbon, or the oxides of these metals [35], [41] are used as catalysts. The catalyst life can be extended, the catalyst consumption decreased, and the product quality enhanced by adding organic solvents that are not miscible with water [32], [34]. The preferred hydrogen pressure is 2 MPa; the hydrogenation can also be performed at atmospheric pressure or at higher pressure up to 6 MPa. The reaction temperature does not exceed 100 – 110 °C.

Reduction of Nitrobenzene. When reducing nitrobenzene in acidic medium [42], the intermediate phenylhydroxylamine [43] rearranges to 2- and 4-aminophenol before it is further reduced to aniline. The main product of this reaction is 4-aminophenol; byproducts are 2-aminophenol, aniline, and 4,4′-diaminodiphenyl ether:

In the past, metals in dilute sulfuric acid were used as reducing agents [44]. Today, the reducing agent is hydrogen in the presence of precious-metal catalysts [43], [45], [46], e.g., palladium or platinum. Other catalysts have been suggested: molybdenum and platinum sulfide [47], [48], and a platinum – ruthenium mixed catalyst [49]. Either the catalysts are used as their oxides, or they are supported on activated carbon.

Dilute aqueous mineral acid is used as reaction medium, for example, dilute sulfuric acid; acidic salts also can be added to the reduction medium [47].

In a two-step process, nitrobenzene first is selectively reduced to phenylhydroxylamine with hydrogen in the presence of Raney copper and in an organic solvent, such as 2-propanol [43]. The product rearranges to 4-aminophenol after addition of dilute sulfuric acid [50].

The addition of *wetting agents* increases the aminophenol yield [51]; these agents must be water soluble and stable in the presence of sulfuric acid. Quaternary ammonium salts that contain at least one alkyl group with at least ten carbon atoms are suitable, e.g., dodecyltrimethylammonium chloride. The reaction usually is performed below 100 °C, either at atmospheric or at higher pressure. Hydrogen is added during the reaction as consumed. The addition of inert organic solvents further increases the yield of 4-aminophenol and the product quality [52].

In another variant, only 88 % of the nitrobenzene is reduced [53]; after that, the reaction mixture consists of two phases with the precious-metal catalyst (palladium on activated carbon) remaining in the unreacted nitrobenzene phase. Therefore, phase separation is sufficient as workup, and the nitrobenzene phase can be recycled directly to the next batch. The aqueous sulfuric acid phase contains 4-aminophenol and byproduct aniline. After neutralization, the aniline is stripped, and 4-aminophenol is obtained by crystallization after the aqueous phase is purified with activated carbon.

Electrolytic reduction also is possible [44], [54–57]; this method causes less concern over pollution than metal – acid reduction systems, but it has not yet found industrial application. Electrolysis of nitrobenzene or phenylhydroxylamine in the presence of sulfuric acid or of azoxybenzene in acid solution yields specifically 4-aminophenol [58].

1.3.2. Substitution

Substitution of various groups by amino or hydroxyl groups is industrially unimportant for the production of 2- and 4-aminophenol [59], but this type of reaction is used for the synthesis of 2- or 4-aminophenol derivatives.

However, 3-aminophenol cannot be obtained easily by reduction. It is made mainly by the reaction of 3-aminobenzenesulfonic acid with sodium hydroxide or by the reaction of resorcinol with ammonia. Substitution of the sulfonic acid group in 3-aminobenzenesulfonic acid is accomplished by caustic soda fusion (5 – 6 h; 240 – 245 °C). The product is purified by vacuum distillation [60].

Alternatively, resorcinol reacts with ammonia [61], for example, in the presence of diammonium phosphate and arsenic pentoxide [62] or ammonium sulfite to form 3-aminophenol. The compound also may be made by hydrolysis of 3-aminoaniline [63], [64].

1.3.3. Purification

Generally, aminophenols can be purified by sublimation at reduced pressure and higher temperature. 3-Aminophenol may be purified by vacuum distillation; to obtain a colorless product sulfur dioxide is added during distillation [65] or the distillate is collected under a blanket of an unreactive liquid of lower density, such as water [66].

Another method for purifying aminophenols is the treatment of their aqueous solutions with activated carbon [67], [68]. During this treatment, sodium sulfite, sodium dithionite, or disodium ethylenediaminotetraacetate [68] is added to increase the quality and stability of the products and to chelate heavy-metal ions that would catalyze oxidation. Addition of sodium dithionite, hydrazine [68], or sodium hydrosulfite [69] also is recommended during precipitation or crystallization of aminophenols.

Contaminants, which are usually present in the 4-aminophenol made by catalytic reduction, can be reduced or even removed completely by a variety of procedures: treatment with 2-propanol [70]; with aliphatic, cycloaliphatic or aromatic ketones [71]; with aromatic amines [72]; with toluene or low molecular mass alkyl acetates [73]; with phosphoric acid, hydroxyacetic acid, hydroxypropionic acid, or citric acid [74]; or by extraction with methylene chloride, chloroform [75], or nitrobenzene [76].

1.4. Storage and Handling

Under atmospheric conditions, 3-aminophenol is the most stable of the three isomers. Both 2- and 4-aminophenol are unstable; they darken on exposure to air and light and should be stored in brown glass containers, preferably in an atmosphere of nitrogen. The use of activated iron oxide in a separate cellophane bag inside the storage container inhibits the discoloration of 4-aminophenol [77]. The salts, especially the hydrochlorides, are more resistant to oxidation and should be used where possible.

1.5. Analysis

Aminophenols have been detected in waste water by investigating UV absorptions at 220, 254, and 275 nm [78] and also in parts per thousand by using potentiometric titrations in a two-phase chloroform–water medium [79] or potentio-argentometric titrations of liberated bromide after reaction with bromine [80]. More specifically, 2-aminophenol can be identified using an iron(II) sulfate–hydrogen peroxide reagent [81] or dimerized in acidic solution to 2-hydroxyisophenoxazin-3-one, as intensively colored dye [82]. 4-Aminophenol can be analyzed by voltammetry [83], [84]. A colorimetric method using 3-cyano-*N*-methoxypyridinium perchlorate as reagent detects 4-aminophenol in the presence of *N*-acetyl-4-aminophenol [85]. 3-Aminophenol has been analyzed colorimetrically by oxidation in base and subsequent extraction of a violet quinoneimide dye [86].

Chromatographic methods for the separation and identification of aminophenols also have been described. Thin layer chromatography provides a rapid and convenient method of separating the isomers from many derivatives, and subsequent spraying with a variety of chromogenic reagents gives additional information [87], [88]. Several gas–liquid [89] and high-pressure liquid [90–92] chromatographic separation techniques have also been reported, and the use of selected-ion mass spectrometry greatly increases detection sensitivity [93], [94].

1.6. Environmental Aspects

As the aminophenols are oxidized easily they tend to remove oxygen from solutions. Hence, if they are released from industrial waste waters into streams and rivers they will deplete the capacity of these environments to sustain aquatic life. The adsorption of aminophenols onto metal ferrocyanides and activated carbons from bituminous coal has met with limited success but may provide a possible means of removal [95], [96]. Biological degradation of 3-aminophenol has been carried out in aeration tanks with adapted microflora from active sludge; the process took 4 months [97]. An enzymatic method for removing aminophenols from waste waters has been described using horseradish peroxidase to cross-link and precipitate the compounds as insoluble polymers [98]. Degradative metabolism by bacteria [99–101] and the im-

mobilization of microbial cells onto Ca-alginate beads [102] may open up a new approach.

1.7. Uses

Both 2- and 4-aminophenols are strong reducing agents and are employed as photographic developers under the trade names of Atomal and Ortol (2-aminophenol); Activol, Azol, Certinal, Citol, Paranol, Rodinal, Unal, and Ursol P (4-aminophenol); they may be used alone or in combination with hydroquinone. The oxalate salt of 4-aminophenol is marketed under the name of Kodelon.

The aminophenols are versatile intermediates and are employed in the synthesis of virtually every class of stain and dye. In addition, 2-aminophenol (Oxidation Base 17; C.I. 76520) is specifically used for shading leather, fur, and hair from grays and browns to yellowish brown. 3-Aminophenol has found application as a hair colorant and as a coupler molecule in hair dyes [103], [104]. 4-Aminophenol is used as an intermediate in the synthesis of pharmaceuticals, as a wood stain imparting a roselike color to timber [105], and as a dyeing agent for fur and feathers.

As a result of the close proximity of the amino and hydroxyl groups on the benzene ring and their ease of condensation with suitable reagents, 2-aminophenol is a principal intermediate in the synthesis of such heterocyclic systems as oxyquinolines, phenoxamines, and benzoxazoles. The last-named compounds have been used as inflammation inhibitors [106]. 3-Aminophenol has found use as a stabilizer of chlorine-containing thermoplastics [107], although its major use is as an intermediate in the production of 4-amino-2-hydroxybenzoic acid, a tuberculostat. Similarly, nitrogen-substituted 4-aminophenols have long been known as antipyretics and analgesics, and the production of these derivatives is a major use of 4-aminophenol.

1.8. Toxicology

In general, aminophenols are irritants. Their toxic hazard rating is slight to moderate, but repeated contamination may cause general itching, skin sensitization, dermatitis, and allergic reactions [108], [109]. Immunogenic conjugates are spontaneously produced on exposure to 2- and 4-aminophenol [110]. Methemoglobin formation with subsequent cyanosis is another possible complication. Inhalation of 4-aminophenol may precipitate this event and also cause bronchial asthma, [111]. 3-Aminophenol is less hazardous than the others. The sulfonated derivatives are less irritating than the unsulfonated compounds.

2-Aminophenol is neuroactive, inducing spike discharges when instilled into the cerebroventricle of the rat [112]. 4-Aminophenol is nephrotoxic and strongly inhibits proximal tubular function [113–115]. Respiration, oxidative phosphorylation, and ATPase activity are inhibited in rat kidney mitochondria [116]. 2-Aminophenol and 4-aminophenol, but not 3-aminophenol, are teratogenic in the hamster [117]. 4-Aminophenol is known to inhibit DNA synthesis and alter DNA structure in human lymphoblasts [118]. The aminophenols also have been shown to be genotoxic, as evidenced by the induction of sister chromatid exchanges and micronucleus tests [119–122].

Obviously, care should be taken in handling these compounds; prolonged exposure should be avoided. Contaminated clothing should be removed immediately and the affected area washed thoroughly with running water for at least 10 min.

2. Aminophenol Derivatives

The derivatives of the aminophenols have important uses in both the photographic and the pharmaceutical industries. They are also extensively applied as precursors and intermediates in the synthesis of more complicated molecules, especially those used in the staining and dye industry. All of the major classes of dyes have representatives that incorporate substituted aminophenols. The varying degrees of ease with which the aminophenols can be diazotized and coupled has led to their use in the manufacture of azo compounds. The sulfonated aminophenols also are employed in this context; these compounds, however, are treated elsewhere (→ Benzenesulfonic Acids and Their Derivatives). Details concerning which aminophenol derivatives and sulfonated compounds

are produced commercially as dye intermediates have been reviewed and are given in the publications listed in reference [123]. The more commonly encountered simple derivatives of the aminophenols can be found in the review articles cited in the references and also in standard organic chemistry texts [124]. A few examples, which have specific uses or are manufactured in large quantities, have been selected for detailed discussion.

2.1. Derivatives of 2-Aminophenol

2-(*N*-Methylamino)phenol (**11**) [*611-24-5*], C_7H_9NO, M_r 123.15, *mp* 99 °C, forms colorless plates; the aqueous hydrochloric acid solution turns reddish brown when $FeCl_3$ solution is added.

Compound **11** is synthesized by reaction of 2-aminophenol with phosgene, alkylation of the intermediate benzoxazolone, and cleavage of *N*-methylbenzoxazolone with hydrochloric acid [125]. Alternatively, 2-*N*-acetyl-*N*-methylaminophenol is heated at 140 °C in the presence of hydrochloric acid [126]:

2-Methoxyaniline (**12**) [*90-04-0*], *o*-anisidine, C_7H_9NO, M_r 123.15, *mp* 6.22 °C, *bp* 224 °C (102.1 kPa), *bp* 105 – 106 °C (1.85 kPa), d_4^{20} 1.0923, $d_4^{98.7}$ 1.0263, n_D^{20} 1.5738, dynamic viscosity η 2.211 mPa · s (55 °C), η 1.051 mPa · s (98.7 °C), dipole moment 1.62 D (vapor), is slightly soluble in water (1.38 wt % at 25 °C).

The compound is produced from 2-methoxynitrobenzene by reduction with iron [127] or by hydrogenation in the presence of precious-metal catalysts [128] (platinum or palladium on activated carbon; solvent: toluene) or of Raney nickel [129] (solvent: methanol or 2-propanol).

12 **13** **14**

2-Ethoxyaniline (**13**) [*94-70-2*], *o*-phenetidine, $C_8H_{11}NO$, M_r 137.18, d_{20}^{20} 1.0513, *bp* 232.5 °C (101.3 kPa), is produced from 2-ethoxynitrobenzene by reduction with iron or by catalytic hydrogenation in the presence of precious-metal catalysts or Raney nickel [130].

2-Acetamidophenol (**14**) [*614-80-2*], 2-hydroxyacetanilide, $C_8H_9NO_2$, M_r 151.16, forms colorless crystals, *mp* 209 °C, that are quite soluble in ethanol and hot water. Production is by acetylation of 2-aminophenol with acetic anhydride [131].

2-Amino-5-nitrophenol (**15**) [*121-88-0*], $C_6H_6N_2O_3$, M_r 154.13, forms orange needles, *mp* 207 – 208 °C, that are sparingly soluble in water. Production is by nitration of benzoxazolone (**16**) and separation from the 2-amino-4-nitrophenol isomer after treatment with hydrochloric acid [132]. It induces Cu(II)-dependent DNA cleavage, presumably via the generation of active oxygen species [133].

2-Amino-4-nitrophenol (**17**) [*99-57-0*], $C_6H_6N_2O_3$, M_r 154.13, 2-hydroxy-5-nitroaniline, forms orange prisms from water that are hydrated with one molecule of water of crystallization, *mp* 80 – 90 °C. They can be

dehydrated over sulfuric acid to the anhydrous form, *mp* 143 – 145 °C, soluble in alcohol, ether, acetic acid, and warm benzene and slightly soluble in water.

Compound **17** is produced commercially by the partial reduction of 2,4-dinitrophenol; this may be achieved electrolytically with vanadium [134] or chemically with polysulfide, sodium hydrosulfide, or hydrazine and copper [135–137]. Alternatively, 2-acetamidophenol or 2-methylbenzoxazole may be nitrated in sulfuric acid to yield a mixture of 4- and 5-nitro derivatives that are then separated and hydrolyzed with sodium hydroxide [138].

The major use of this compound is in the production of mordant and acid dyes. 2-Amino-4-nitrophenol also has found limited use as an antioxidant and light stabilizer in butyl rubbers and as a catalyst in the manufacture of hexadiene.

2-Amino-4-nitrophenol has been shown to be a skin irritant and continuous exposure should be avoided. Toxicologic studies have shown it to be nonaccumulative [139] but suggest it is carcinogenic [133].

2-Amino-4,6-dinitrophenol (**18**) [*96-91-3*], $C_6H_5N_3O_5$, M_r 199.13, 4,6-dinitro-2-aminophenol, picramic acid, forms dark red needles from alcohol and prisms from chloroform, *mp* 169 – 170 °C. The compound flashes at 210 °C in contact with an open flame, ignites rapidly, and burns relatively fast. 2-Amino-4,6-dinitrophenol is soluble in glacial acetic acid, water, alcohol, benzene, and aniline and sparingly soluble in ether and chloroform.

The compound can be prepared from 2,4,6-trinitrophenol (picric acid) by reduction with sodium hydrosulfide [140], with ammonia – hydrogen sulfide followed by acetic acid neutralization of the ammonium salt [141], with ethanolic hydrazine and copper [137], or electrolytically with vanadium sulfate in alcoholic sulfuric acid [134]. Heating 4,6-dinitro-2-benzamidophenol in concentrated HCl at 140 °C also yields picramic acid [142]. It is a major intermediate in the manufacture of colorants, especially mordant dyes. It has also been used as an indicator dye in titrations (yellow with acid, red with alkali) and as a reagent for albumin determination. The induction of sister chromatid exchange and micronuclei formation by this compound suggest potential health hazards [143], [144].

18

19

2,4-Diaminophenol (**19**) [*95-86-3*], 4-hydroxy-*m*-phenylenediamine, $C_6H_8NO_2$, M_r 124.14, forms leaflets that darken on exposure to air and melt at 78 – 80 °C with decomposition. The compound is soluble in acid, alkali, alcohol, and acetone and sparingly soluble in chloroform, ether, and ligroin. 2,4-Diaminophenol usually is sold as the sulfate [*72556-58-2*] (Diamol) or dihydrochloride salt [*137-09-7*] (Acrol, Amidol).

2,4-Diaminophenol can be prepared from 2,4-dinitrophenol by catalytic hydrogenation or, less conveniently, by metal reduction in acid solution (Béchamp method) [145–150]. Alternatively, electrolytic reduction and subsequent hydroxylation of 1,3-dinitrobenzene or 3-nitroaniline in sulfuric acid can be undertaken [151–153].

The dihydrochloride salt is used as a photographic developer. It also is applied as an intermediate in the manufacture of fur dyes, in hair dyeing, as a reagent in testing for ammonia and formaldehyde, and as an oxygen scavenger in water to prevent boiler corrosion [154].

2-Amino-4-chlorophenol [*95-85-2*], C_6H_6ClNO, M_r 143.58, forms colorless plates, *mp* 139 – 140 °C, that are extremely sensitive to oxidation when wet. For its production 2,5-dichloronitrobenzene is converted to 4-chloro-2-nitrophenol by reaction with sodium hydroxide; this product is then reduced either with iron [155], with hydrazine, or with hydrogen [156] in the presence of Raney nickel or platinum catalysts.

2-Amino-4-methylphenol [*95-84-1*], C_7H_9NO, M_r 123.15, forms crystals, *mp* 135 °C (decomp.), that are almost insoluble in cold water. The compound is quite soluble in ethanol, diethyl ether, and chloroform but is almost in-

soluble in benzene. 2-Amino-4-methylphenol is obtained by reduction of 2-nitro-4-methylphenol either with hydrazine or catalytically [157].

2-Methoxy-5-methylaniline (**20**) [*120-71-8*], 2-amino-4-methylanisole, 3-amino-4-methoxytoluene, $C_8H_{11}NO$, M_r 137.18, forms needles or plates, *mp* 52 °C, *bp* 235 °C (101.3 kPa), that can be steam distilled. The compound is quite soluble in ethanol, diethyl ether, and benzene, but not very soluble in cold water. Production is by alkylation of 4-methyl-2-nitrophenol and subsequent reduction with iron [158].

20

2-Methoxyacetanilide (**21**) [*93-26-5*], $C_9H_{11}NO_2$, M_r 165.19, crystallizes as needles, *mp* 86.5 °C, *bp* 303 – 305 °C (101.3 kPa). The compound is quite soluble in acetic acid and hot water. Production is by acetylation of 2-methoxyaniline with acetic anhydride.

2-Methoxy-5-chloroaniline (**22**) [*2401-24-3*], C_7H_8ClNO, M_r 157.61, *mp* 84 °C, is quite soluble in ethanol and can be steam distilled. Production is by reduction of the corresponding nitro compound with iron [159].

21

22

23

24

2-Amino-4,6-dichlorophenol (**23**) [*527-62-8*], $C_6H_5Cl_2NO$, M_r 178.03, is sparingly soluble in water and ethanol and decomposes when heated above 109 °C. Industrial production is by reduction of the corresponding nitro compound with iron [160] or with hydrazine.

2-Methoxy-4-nitroaniline (**24**) [*97-52-9*], $C_7H_8N_2O_3$, M_r 168.15, *mp* 140 – 142 °C, is prepared by acetylation and subsequent nitration of 2-methoxyaniline to form intermediate **33** , which is then deacetylated to **24**.

2-Methoxy-5-nitroaniline (**25**) [*99-59-2*], $C_7H_8N_2O_3$, M_r 168.15, *mp* 118.5 – 119 °C, is prepared either by partial reduction of 2,4-dinitroanisole (**26**) with ammonium or sodium sulfide [161] or by nitration of 2-methoxyaniline (**27**) [162].

26 **25** **27**

2-Amino-4-chloro-5-nitrophenol (**28**) [*6358-07-2*], $C_6H_5ClN_2O_3$, M_r 188.58, forms yellow needles that darken when heated above 200 °C and decompose above 225 °C. The compound is scarcely soluble in hot water but quite soluble in ethanol. Industrial production is by reaction of 2-amino-4-chlorophenol with phosgene, nitration of the product 5-chlorobenzoxazolone (**29**) with nitric acid to form 5-chloro-4-nitrobenzoxazolone (**30**), and subsequent hydrolysis with sodium hydroxide [163].

2-Amino-6-chloro-4-nitrophenol (**31**) [*6358-09-4*], $C_6H_5ClN_2O_3$, M_r 188.58, crystallizes from water in yellow needles that contain 1 mol of water. Dehydration occurs when the needles are heated above 100 °C; the crystals turn scarlet and finally melt at 160 °C. The compound is sparingly soluble in water and quite soluble in ethanol and diethyl ether. Industrial production is by partial reduction of 6-chloro-2,4-dinitrophenol with sodium hydrosulfide or ammonium sulfide [164].

31 32

3-Amino-4-methoxybenzoic acid (**32**) [*2840-26-8*], $C_8H_9NO_3$, M_r 167.16, *mp* 204 – 205 °C, forms needles or prisms that are sparingly soluble in cold water and also in boiling water (0.12 wt %). The crystals are sparingly soluble in diethyl ether and quite soluble in hot ethanol. Production is by reduction of the corresponding nitro compound.

4-Amino-2-methoxy-acetanilide (**34**) [*5329-15-7*], 4-acetamido-3-methoxyaniline, $C_9H_{12}N_2O_2$, M_r 180.2, *mp* 120 – 121 °C, is quite soluble in ethanol, ethyl acetate, acetone, and chloroform. The solubility in diethyl ether is low. Production is by acetylation of 2-methoxyaniline and subsequent nitration with nitric acid [165]. Nitro compound **33** is then reduced with iron in dilute acetic acid [166].

2-Methylbenzoxazole (**35**) [*95-21-6*], C_8H_7NO, M_r 133.16, *mp* 8.5 – 10 °C, *bp* 178 °C, n_D^{20} 1.5497, is made by cyclization of 2-acetamidophenol. Its chief use is for the production of 2-amino-5-nitrophenol (**15**).

35

Orthocaine [*536-25-4*], 3-amino-4-hydroxybenzoic acid methyl ester, methyl 3-amino-4-hydroxybenzoate, Orthoform New, $C_8H_9NO_3$, M_r 167.16, *mp* 143 °C, is almost insoluble in cold, but soluble in hot water, and very soluble in alcohol, ether, and dilute alkali. For preparation, see [167], [168].

The compound is used as a topical anesthetic.

Acetarsone [*97-44-9*], 3-acetamido-4-hydroxyphenylarsonic acid, acetarsol, stovarsol, $C_8H_{10}AsNO_5$, M_r 275.08, *mp* 240 – 250 °C (decomp.), is practically insoluble in alcohols or dilute acids, slightly soluble in water, and freely soluble in dilute aqueous alkali. For its preparation, see [169], [170].

Salts of acetarsone are used in the treatment of intestinal amoebiasis, trade name Acetarsol, of vaginal trichomoniasis, trade name S.V.C. (May and Baker), and as a constituent of a mouthwash, trade name Pyrex (Bengué). Because of acetarsone's toxicity, safer drugs have been developed; lethal dose LD_{50} 150 mg/kg (rabbit, oral).

2.2. Derivatives of 3-Aminophenol

3-(*N,N*-Dimethylamino)phenol (36) [*99-07-0*], 3-hydroxydimethylaniline, $C_8H_{11}NO$, M_r 137.18, forms white needles, *mp* 87 °C. Boiling points quoted at various pressures are 265 – 268 °C (101.3 kPa), 206 °C (13.3 kPa), 194 °C (6.7 kPa), 153 °C (0.7 kPa). The compound is soluble in alkali, mineral acid, ethanol, ether, acetone, and benzene and practically insoluble in water.

36

3-(*N,N*-Dimethylamino)phenol can be prepared by heating resorcinol with an aqueous solution of dimethylamine and its hydrochloride at 200 °C under pressure for 12 h [171], [172]. Alternatively, the treatment of dimethylaniline with oleum at 55 – 60 °C, followed by fusion with sodium hydroxide at 270 – 300 °C, gives 3-(*N,N*-dimethylamino)phenol [173]. In addition, 3-aminophenol may be methylated with dimethyl sulfate under neutral conditions [174] or its hydrochloride salt heated with methanol at 170 °C under pressure for 8 h to give the desired product [175]. The compound is used primarily as an intermediate in the production of basic (Red 3 and Red 11) and mordant (Red 77) dyes.

3-(*N*-Methylamino)phenol (37) [*14703-69-6*], C_7H_9NO, M_r 123.15, *bp* 170 °C (1.6 kPa), is easily soluble in ethyl acetate, ethanol, diethyl ether, and benzene; it is sparingly soluble in cold water, better in hot water. Industrial synthesis is by heating 3-(*N*-methylamino)benzenesulfonic acid with sodium hydroxide at 200 – 220 °C [176] or by the reaction of resorcinol with methylamine in the presence of aqueous phosphoric acid at 200 °C [177].

3-(*N,N*-Diethylamino)phenol (38) [*91-68-9*], $C_{10}H_{15}NO$, M_r 165.23, forms rhombic bipyramidal crystals, *mp* 78 °C, *bp* 276 – 280 °C (101.3 kPa), *bp* 209 – 211 °C (1.6 kPa). Industrial synthesis is analogous to the previously described synthesis of 3-(*N,N*-dimethylamino)phenol: from resorcinol and diethylamine, by reaction of 3-(*N,N*-diethylamino)benzenesulfonic acid with sodium hydroxide, or by alkylation of 3-aminophenol hydrochloride with ethanol.

38

39

3-(*N*-Phenylamino)phenol (39) [*101-18-8*], $C_{12}H_{11}NO$, M_r 185.22, *mp* 81.5 – 82 °C, *bp* 340 °C (101.3 kPa), is slightly soluble in ethanol, diethyl ether, acetone, benzene, and water. The compound is made by heating resorcinol and aniline at 200 °C in the presence of aqueous phosphoric acid [62] or calcium chloride [178]. In another process, 3-aminophenol is heated with aniline hydrochloride at 210 – 215 °C [179].

4-Amino-2-hydroxybenzoic acid (40) [*65-49-6*], 4-aminosalicylic acid (PAS), $C_7H_7NO_3$, M_r 153.13, white crystals from alcohol, melts at 150 – 151 °C with effervescence

and darkens on exposure to light and air. A reddish-brown crystalline powder is obtained on recrystallization from ethanol – ether. 4-Amino-2-hydroxybenzoic acid is soluble in dilute solutions of nitric acid and sodium hydroxide, alcohol, and acetone; slightly soluble in water and ether; and virtually insoluble in benzene, chloroform, or carbon tetrachloride. It is unstable in aqueous solution and decarboxylates to form 3-aminophenol. Because of the instability of the free acid it is usually prepared as the hydrochloride salt, *mp* 224 °C (decomp.), dissociation constant pK_a 3.25.

40

4-Amino-2-hydroxybenzoic acid is manufactured by carboxylation of 3-aminophenol under pressure with ammonium carbonate at 110 °C [180] or with potassium bicarbonate and carbon dioxide at 85 – 90 °C [181] and subsequent acidification.

The major use of this compound is as a bacteriostatic agent against tubercle bacilli. The compound also is used as an adjunct to streptomycin and isoniazid. The free acid and its sodium, potassium, and calcium salts are marketed under many trade names. Up to 10 – 15 g of the sodium salt may be administered each day, although prolonged use may give rise to toxic symptoms. Oral LD_{50} of the free acid in mice is 4 g/kg.

2.3. Derivatives of 4-Aminophenol

4-(*N*-Methylamino)phenol (41) [*150-75-4*], 4-hydroxy-*N*-methylaniline, C_7H_9NO, M_r 123.15, forms needles from benzene, *mp* 87 °C, *bp* 168 – 169 °C (2 kPa); it is slightly soluble in alcohol and insoluble in ether.

Industrial synthesis involves the decarboxylation of *N*-(4-hydroxyphenyl)glycine (**47**) at elevated temperature in such solvents as chlorobenzene – cyclohexanone [182]. It also can be prepared by the methylation of 4-aminophenol [183] or from methylamine by heating with 4-chlorophenol and copper sulfate at 135 °C in aqueous solution [184] or with hydroquinone at 200 – 250 °C in alcoholic solution [185], [186].

Its chief use is as a component in photographic developers. Because the free compound is unstable in air and light, it usually is marketed as the sulfate salt [*55-55-0*], Metol, *mp* 260 °C (decomp.). It also finds application as an intermediate for fur and hair dyes and, under certain circumstances, as a corrosion inhibitor for steel. Prolonged exposure to 4-(*N*-methylamino)phenol has been associated with the development of dermatitis and allergies.

4-(*N,N*-Dimethylamino)phenol (42) [*619-60-3*], 4-hydroxydimethylaniline, $C_8H_{11}NO$, M_r 137.18, forms large rhombic crystals from ether – hexane or ether – ligroin that melt at 75 – 76 °C, *bp* 101 – 103 °C (66.7 Pa). The compound forms a salt with sulfuric acid, *mp* 208 – 210 °C [187], [188].

Methylation of 4-aminophenol with a methyl halide under pressure produces 4-(*N,N*dimethylamino)phenol. The major competing product, 4-hydroxyphenyltrimethyl ammonium halide (or the corresponding base), also yields 4-(*N,N*-dimethylamino)phenol on distillation. Alternatively, it can be synthesized by dealkylation of 4-methoxydimethylaniline with hydroiodic acid at reflux temperature for 10 h [189] or by the photodecomposition of 4-dimethylaminobenzenediazonium tetrafluoroborate [187].

The compound is an intermediate in several synthetic reactions and recently has found extensive use in experimental toxicity studies in animals. It has been shown to cause methemoglobinemia; its metabolism in humans has been discussed in [190–195].

41

42

43

4-Hydroxyacetanilide (**43**) [*103-90-2*], 4-acetamidophenol, acetaminophen, paracetamol, forms large white monoclinic prisms from water that melt at 169 – 171 °C. The compound is odorless and has a bitter taste. 4-Hydroxyacetanilide is insoluble in petroleum ether, pentane, and benzene; slightly soluble in ether and cold water; and soluble in hot water, alcohols, dimethylformamide, 1,2-dichloroethane, acetone, and ethyl acetate. The dissociation constant, pK_a, is 9.5 (25 °C).

Production is by the acetylation of 4-aminophenol. This can be achieved with acetic acid and acetic anhydride at 80 °C [196], [197], with acetic anhydride in pyridine at 100 °C [198], with acetyl chloride and pyridine in toluene at 60 °C [199], or by the action of ketene in alcoholic suspension [200]. 4-Hydroxyacetanilide also may be synthesized directly from 4-nitrophenol. The available reduction – acetylation systems include tin with acetic acid [201], hydrogenation over Pd – C in acetic anhydride [202], and hydrogenation over platinum in acetic acid [203]. Other routes include rearrangement of 4-hydroxyacetophenone hydrazone with sodium nitrite in sulfuric acid [204] and the electrolytic hydroxylation of acetanilide [205].

4-Hydroxyacetanilide is used as an intermediate in the manufacture of azo dyes and photographic chemicals. The compound possesses antipyretic and analgesic properties and is used widely in this context. The oral LD_{50} in rats is 3.7 g/kg.

4-Methoxyaniline [*104-94-9*], C_7H_9NO, has M_r 123.55, *mp* 58.5 °C, *bp* 123.2 – 123.5 °C (1.9 kPa), dipole moment 1.8 D (benzene), d_4^{55} 1.092, n_D^{67} 1.5559, viscosity η 3.215 mPa · s (55 °C). For its industrial production 4-nitroanisole is reduced either with sodium sulfide [206] or with hydrogen in the presence of precious-metal catalysts or Raney nickel.

4-Ethoxyaniline [*156-43-4*], $C_8H_{11}NO$, M_r 137.18, *mp* 2.4 °C, *bp* 249.9 °C (101.3 kPa), $d_4^{14.9}$ 1.0652, $n^{15.9}{}_{\alpha}$ 1.5572, is a colorless compound at room temperature when pure; in the light or in the presence of air, the liquid turns brown. 4-Ethoxyaniline is slightly soluble in water.

Industrial production of 4-ethoxyaniline is by reduction of 4-nitrophenetole with iron [207] or with hydrogen under pressure in the presence of a catalyst. Alternatively, 4-chlorophenetole is heated with aqueous ammonia in the presence of copper(I) oxide at 225 °C; the yield of 4-ethoxyaniline is 85 % [208].

4-Ethoxyacetanilide (**44**) [*62-44-2*], phenacetin, *p*-acetophenetidine, 4-acetamidophenetole, $C_{10}H_{13}NO_2$, M_r 179.21, is a white crystalline powder, *mp* 134 – 135 °C. The compound is odorless and has a slightly bitter taste; it is sparingly soluble in cold water and more soluble in hot water, alcohol, ether, and chloroform. At relative humidities between 15 and 90 % the equilibrium moisture content is about 2 % (25 °C).

44

The main production route to 4-ethoxyacetanilide is by catalytic reduction of 4-nitrophenetole with hydrogen and subsequent acetylation using acetic anhydride. The compound also can be synthesized by ethylating 4-nitrophenol with ethyl sulfate in alkali, reducing the nitro group to an amino group with iron in acid, and then acetylating by boiling with glacial acetic acid [209]. Alternatively, 4-aminophenol may be ethylated with ethyl iodide in alcoholic alkali; the resulting 4-phenetidine is then acetylated. The acetylation also may be carried out first, followed by the ethylation.

4-Ethoxyacetanilide possesses both antipyretic and analgesic properties but is of little value for the relief of severe pain. Its use for prolonged periods should be avoided because one of its minor metabolites (2-hydroxyphenetidine) is nephrotoxic and may be involved in the formation of methemoglobinemia. The oral LD_{50} in rats is 1.65 g/kg [210].

5-Aminosalicylic acid (**45**) [*89-57-6*], 5-amino-2-hydroxybenzoic acid, $C_7H_7NO_3$, M_r 153.13, forms colorless crystals that turn

brown on heating above 250 – 260 °C and melt at 283 °C (decomp.). The crystals are insoluble in ethanol and cold water and sparingly soluble in hot water.

46

45

The compound is made by reduction of 3-nitrobenzoic acid at 115 – 145 °C and 3.5 MPa in dilute sulfuric acid and in the presence of platinum catalyst. The intermediate hydroxylamine derivative (**46**) rearranges to **45** under these conditions [211]. Alternatively, 5-nitrosalicyclic acid is reduced, for example, with zinc in hydrochloric acid [212].

***N*-(4-Hydroxyphenyl)glycine (47)**

[*122-87-2*], 4-hydroxyphenylaminoacetic acid, 4-oxyanilinoacetic acid, photoglycine, $C_8H_9NO_3$, M_r 167.16, forms aggregate spheres or shiny leaflets from water; it turns brown at 200 °C, begins to melt at 220 °C, and melts completely with decomposition at 245 – 247 °C. The compound is soluble in alkali and mineral acid and sparingly soluble in water, glacial acetic acid, ethyl acetate, alcohol, ether, acetone, chloroform, and benzene.

N-(4-Hydroxyphenyl)glycine can be prepared from 4-aminophenol and chloroacetic acid [213], [214] or by alkaline hydrolysis of the corresponding nitrile with subsequent elimination of ammonia [215].

N-(4-Hydroxyphenyl)glycine is used as a photographic developer under the trade names of Glycine, Iconyl, and Monazol. It also is applied as a photoresist in the dye industry and serves as an intermediate in the production of 4-(*N*-methylamino)phenol (Metol) by liberation of CO_2. *N*-(4-Hydroxyphenyl)glycine is used in analytical chemistry for the determination of iron, phosphorus, and silicon and as an acid indicator in bacteriology. Prolonged use of this compound may result in kidney damage [216].

47

48

4-Amino-2,6-dichlorophenol (48)

[*5930-28-9*], $C_6H_5Cl_2NO$, M_r 178.03, can be sublimed and melts at 167 °C. The compound is soluble in ethanol, diethyl ether, acetone, and acetic acid; it is sparingly soluble in benzene and almost insoluble in water.

1. Introduction

Amino resins are condensates formed when carbonyl compounds react with compounds containing amino, imino, or amide groups, liberating water. Before they have hardened, these products consist principally of oligomers, which are also called prepolymers.

A very large number of carbonyl- and nitrogen-containing compounds yield condensates of relatively low molecular weight. The type of interaction is determined by the functional groups. Among such compounds, formaldehyde, urea, and melamine have become the most important, especially because of their relatively low prices. These products are obtained by large-scale production in modern industrial plants. The amino resins offer technical advantages in many applications.

History. The history of amino resins began with the synthesis of the two main raw materials, urea and formaldehyde; the former was prepared by F. Wöhler in 1824, and the latter by A. Butlerov in 1859. However, the first investigations of urea – formaldehyde (UF) resins were not carried out until about 1880. The first reaction products were reported by B. Tollens (1884) and C. Goldschmidt (1887), and the basic chemistry of the amino resins was established about 1908 [14].

F. Pollack and K. Ripper (1921) synthesized a clear transparent material, which they called "Pollopas." This product never became commercially important, but it did give rise to a number of experiments. The first commercial products, manufactured by E. C. Rossiter of British Cyanides Co. in 1924 and 1925, led to molding materials still in use today.

The melamine resins were introduced in Germany by Henkel in 1935 [15]. Their properties are similar to those of the urea – formaldehyde resins, but the resins are of higher quality. For example, they are chemically stable after the resin has hardened and become insoluble.

An ever-increasing number of mixtures of urea – formaldehyde and melamine – formaldehyde resins are produced for the most diverse

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a02_115

uses. Lower costs and the better performance of the products made from these mixtures account for their popularity.

Amino resins find their major use as adhesives. They are used in the production of plywood, waferboard, strandboard, and particle board. Other types are employed for the production of laminated beams and parquet flooring, and for furniture assembly. Amino resins are also used to strengthen paper, to produce molding compounds and the flexible backing of carpets, as leather auxiliaries and soil conditioners, and for protective surface coatings.

2. Physical Properties

Amino resins are available commercially as concentrated solutions or solids, e.g. powders. The solutions generally contain water as a solvent, but in the surface-coating resins the solvents are alcohols. The solutions range from colorless and clear to milky and cloudy and are tacky to the touch. Their viscosities are substantially higher than that of water, from 20 to 70000 mPa · s – in general from 200 to 2000 mPa · s – measured at 20 °C. The amino resins can be odorless or, depending on the content of free formaldehyde, have a more or less sharp odor. The densities of the solutions at the commercially available concentrations of 55 – 80 % solids are from 1.23 to 1.31 g/cm^3. An important property of the resins is the amount of water that can be added without precipitating solids. At relatively low temperatures, i.e., below about 20 °C, pronounced cloudiness and an unusually large increase in viscosity are observed in many cases.

Some resin solutions exhibit the phenomenon of pseudoplasticity (thixotropy), which may or may not be desirable. Thixotropy means that the viscosity decreases as the shearing force increases [16], [17].

In powder form amino resins are white. In the spray-dried, commercially available form they have a particle size generally of 15 – 70 µm, but always < 200 µm. This particle size is a result of the spray-drying process [18]. The bulk density of the commercially available products is 0.5 – 0.8 kg/L. The powder resins dissolve in water to give milky liquids. Flourlike additives can be mixed with some resins, which then assume the color of the additive to a greater or lesser extent.

3. Chemical Properties

Even when they are prepared from only two components, the amino resins are mixtures of various substances. For example, in the case of urea – formaldehyde resins the major components of the mixture are various hydroxymethyl compounds and oligomers composed of different combinations of basic units and substituted basic units. These oligomers are of different sizes. As an approximation, the basic unit can be described as methylene – urea (**1**), which can carry various substituents at the nitrogen atoms:

1

Hence, it is not possible to attribute specific chemical properties to these substances, as in the case of a pure compound.

However, some chemical properties are common to all or most amino resins.

The chemical properties given below are important with regard to processing the resins. The equations given for urea – formaldehyde also apply in principle to other reactants employed for these classes of products.

– Formaldehyde is slowly split off from hydroxymethyl compounds and undergoes addition reactions with other amino groups in accordance with the equilibrium equation [19], [20]:

$$H_2N\text{–}CO\text{–}NH_2 + CH_2O \rightleftharpoons H_2N\text{–}CO\text{–}NH\text{–}CH_2OH$$

– Hydroxymethyl compounds undergo slow condensation in the absence of heat or react with urea to give methylene compounds, such as methylene – diurea or methylene – oligourea:

$$H_2N\text{–}CO\text{–}NH\text{–}CH_2OH + H_2N\text{–}CO\text{–}NH_2 \longrightarrow H_2N\text{–}CO\text{–}NH\text{–}CH_2\text{–}NH\text{–}CO\text{–}NH_2 + H_2O$$

$$2\,H_2N\text{–}CO\text{–}NH\text{–}CH_2OH \longrightarrow H_2N\text{–}CO\text{–}NH\text{–}CH_2\text{–}NH\text{–}CO\text{–}NH_2 + CH_2O + H_2O$$

These reactions are responsible for the gradual increase in viscosity that amino resins undergo during storage [21].

– It is assumed that bis-methylene – urea ethers (**2**) are formed [13, p. 324], [20], [22], but amino resin solutions contain only small amounts of these ethers. Under certain production conditions cyclic ethers, so-called urones (**3**), also occur.

– Amino resin solutions generally are rendered slightly alkaline, i.e., pH 8 – 9, in order to stabilize them, but the pH slowly decreases as formic acid is formed.

These reactions, especially condensation with the formation of methylene bridges, are accelerated by acid catalysts and elevated temperatures. Hence, in processing amino resins, acids or acid-forming substances are important as hardeners that accelerate the condensation. Alkali-catalyzed condensation [13, pp. 331 – 332], [23] is of no practical importance.

The hydroxymethyl groups can be converted with alcohols to the corresponding ethers. This reaction is utilized in surface-coating resins and to a lesser extent in glues for particle board and in textile and paper auxiliaries.

The free formaldehyde, which is present in concentrations of from 0.1 % to about 2 %, is of practical importance in many cases because it reacts with ammonium salts of acids to give hexamethylenetetramine and the free acid, which acts as a hardener.

Resin powders also condense over time to give relatively high molecular mass products, but in this case the reaction is slower by a factor of at least five.

4. Raw Materials

The principal carbonyl component is formaldehyde, but furfural and glyoxal are employed also. Only formaldehyde is important in industrial production. Other aldehydes are employed, but these play a very minor role.

The most important amine-containing components are urea and melamine, but thiourea, guanidine, cyanamide, and dicyanodiamide, and to a lesser extent acid amides, guanamines, and aniline, are employed also. Further components include the derivatives of these compounds, e.g., substituted ureas.

Relevant information on raw materials used to produce amino resins can be found in [1, pp. 3 – 85].

Products that are added in relatively small amounts to effect slight but often important changes in the properties are called modifiers. These include alcohols, amines, aminoalcohols, and a very large variety of other organic and inorganic substances [1, pp. 7 – 122].

Finally, it should also be mentioned that inert inorganic salts sometimes are added during the production or processing of glue resins [8, p. 34], [24], [25].

Formaldehyde, CH_2O, M_r 30.03, [*50-00-0*] (production and properties → Formaldehyde). In the production of amino resins, formaldehyde is used either in the form of solid paraformaldehyde, in aqueous solution, or as a urea – formaldehyde precondensate containing from 4 to 5 mol of formaldehyde per mole of urea. Paraformaldehyde is a mixture of hydrated polyoxymethylene molecules, with a degree of polymerization of 6 – 100 units. The melting point ranges from 120 to 170 °C, depending on the molecular mass.

$$HO-[CH_2O]_n-H \quad n = 6-100$$

The most frequently used commercial form is a 30 – 55 % aqueous solution of formaldehyde. These solutions are clear, caustic, and inflammable, have a sharp odor, and are infinitely miscible with water. Formaldehyde is present in aqueous solutions predominantly as the hydrate (HO–CH_2–OH), which is in equilibrium with its oligomers:

$$n\,CH_2(OH)_2 \rightleftharpoons HO(CH_2O)_nH + (n-1)\,H_2O$$

Depending on the method of production, the solutions are contaminated with a few hundredths of a percent of formic acid and from 0.5 to 2 % of

methanol. The content of formic acid and methanol increases during storage, as a result of the Cannizzaro reaction:

$$2\,CH_2O + H_2O \longrightarrow HCOOH + CH_3OH$$

Moreover, on long-term storage at low temperatures, paraformaldehyde separates as a hazy suspension or a precipitate. This process is retarded by the addition of stabilizers, e.g., up to 12 % of methanol or triazine derivatives.

Depending on the concentration and the methanol content, the flash point is about 60 – 85 °C. The regulations governing flammable liquids do not apply to aqueous formaldehyde solutions.

Formaldehyde solutions can be stored and transported in containers made of stainless steel, aluminum, polyester resin, or appropriately lined iron.

Finally, aqueous solutions of urea – formaldehyde precondensates also are employed. Commercially available solutions contain from 70 to 80 % of the active ingredients, calculated as urea and formaldehyde. The molar ratio of formaldehyde to urea ranges from 4 : 1 to 5 : 1, and the mass ratio is therefore 2 : 1 to 2.5 : 1. These solutions are substantially more resistant to polymer precipitation than are pure formaldehyde solutions. In the urea – formaldehyde precondensates, the major part of the formaldehyde is present in the form of urea – hydroxymethyl compounds, a smaller part as formaldehyde or its oligomers in the hydrated form, and a very small part as condensates. In this last case, the urea molecules are linked mainly via methylene bridges.

Biologic Effect. The maximum allowable concentration (MAK value) recommended by the Senate Committee of the Deutsche Forschungsgemeinschaft (German Research Organization) in the Federal Republic of Germany is 1 ppm. The corresponding values for the United States of America (given by OSHA) and Japan are 3 ppm and 2 ppm, respectively. At present, regulations vary from country to country (→ Formaldehyde, Chap. 10.).

Other Aldehydes. Other aldehydes play a minor role. *Glyoxal* [*107-22-2*] is available commercially in the form of 30 – 40 % aqueous solutions. The purity is 97 – 99 %. Depending on the production method, the solutions contain 0.1 – 0.2 % acid constituents. The color number should have a maximum value of 15 (APHA). Glyoxal is hydrated in the aqueous solution.

Urea [*57-13-6*], carbamide, diamide of carbonic acid, H_2NCONH_2, M_r 60.06 (→ Urea).

Urea is available commercially as a white crystalline product or as prills. For amino resin production, a technical-grade product is usually adequate.

It should be noted that fertilizer urea frequently is contaminated with ammonium salts, and these may act as hardeners and cause the glue mixture to solidify even in the production stage. Furthermore, the prilled urea can be mixed with sulfur or formaldehyde to keep it free flowing. Sulfur-coated urea is not recommended for resin production. The formaldehyde forms insoluble condensates on the surface of the prills, and these condensates can lead to a slight cloudiness when the prills are dissolved.

The dissolution of urea in water is an endothermic process. The enthalpy of solution (ΔH) is + 257.5 J/g, measured at 10 °C in a 20-fold amount of water.

In the production of amino resins, urea is employed in solid form, in solution, or as a urea – formaldehyde precondensate.

Thiourea [*62-56-6*], thiocarbamide, NH_2CSNH_2, M_r 76.12 (→ Thiourea).

Thiourea is a relatively expensive raw material and is therefore not very important industrially. Apart from its use in special products, it serves only as a modifier, for example, in impregnating resins. Thiourea improves the resin properties, e.g., hardness, surface gloss, and water resistance.

The melting point of thiourea is 180 °C. Its solubility in water is 9 % at 100 °C, substantially lower than that of urea.

Substituted Ureas. Cyclic ethylene ureas and propylene ureas (2-oxoimidazolidine and 2-oxohexahydropyrimidine) are employed for the preparation of textile auxiliaries. Because of their high price and their limited ability to form condensates, they are not used in large amounts for any other purposes.

Melamine [*108-78-1*], 2,4,6-triamino-1,3,5-triazine, cyanurotriamide, M_r 126.13 (→ Melamine and Guanamines). Melamine (**4**) is a white powder that sublimes on heating. The particle diameter depends on the production process and varies from 5 to 300 µm. The rate of solubility in formaldehyde solutions depends on the particle size and is an important parameter given in the information leaflets of melamine producers. The color number of a 50 % melamine – formaldehyde solution may not exceed 20 (APHA). This is important with respect to raw materials for surface coatings and to impregnating resins.

Melamine derivatives, e.g., benzoguanamine (**5**), are employed as modifiers.

4

5

Modifiers. A very large number of additives from all areas of organic and inorganic chemistry have been used to modify amino resins; most of these additives are no longer important [1, pp. 107 – 122]. Aliphatic alcohols, sugars, polysaccharides, and caprolactam are additives for special purposes and are still used today.

5. Production

5.1. Principle Aspects

Amino resin production consists of two stages: *hydroxymethylation* and *condensation*. Depending on the reaction conditions, hydroxymethylation is accompanied to a greater or lesser extent by condensation. The following equations illustrate the process in a simple case, for example, for formaldehyde plus urea:
Hydroxymethylation:

$$NH_2CONH_2 + 2\,CH_2O \rightleftharpoons HOCH_2\text{–}NHCONH\text{–}CH_2OH$$

Condensation:

$$HOCH_2\text{–}NHCONH\text{–}CH_2OH + NH_2CONH_2 \longrightarrow HOCH_2\text{–}NHCONH\text{–}CH_2\text{–}NHCONH_2 + H_2O$$

Further condensation leads to longer chains of the basic unit

$$\text{–}\underset{|}{N}\text{–}CO\text{–}\underset{|}{N}\text{–}CH_2\text{–}.$$

Hydroxymethylation is carried out in a slightly alkaline or slightly acidic medium, whereas the condensation requires a more strongly acidic solution. The process for the production of the resin is continued until the resulting product is an oligomeric mixture that is still soluble or fusible. It is protected against further condensation by rendering the medium alkaline. Condensation of the resin by means of acid catalysis, i.e., cross-linking to give a substantially infusible product, is not carried out until the resin is put to use. This process is called *curing*. However, free hydroxymethyl groups are present even in this state.

The monomolecular and hydroxymethyl compounds with low degrees of polymerization and up to six urea – formaldehyde units are virtually all known and can be prepared in pure form [1, p. 20]. Aqueous solutions of the oligomers with low degrees of polymerization do not have a sufficiently long shelf life. Only when the concentrations of hydroxymethyl and NH_2 groups are reduced by partial condensation or when the products are present in solid form do they possess an industrially useful shelf life, i.e., several weeks or more.

Condensations carried out in an excess of an alcohol, such as methanol or butanol, with the addition of acid and removal of water as necessary, produce curable etherified amino resins. These are soluble in nonaqueous solvents and can be mixed with alkyd resins, epoxy resins, etc. They are used as starting materials in the production of surface coatings.

Resin glues based on urea, melamine, or both have been subjected to partial etherification to stabilize them against further condensation [26–28].

Preventing the resins from solidifying during the production process and selectively achieving certain properties – such as long shelf life, low formaldehyde content, strength, and resistance to swelling of particle board after curing – are the basic difficulties encountered. Frequently, novel properties are required on short notice by the market.

5.1.1. Hydroxymethylation

Hydroxymethylation can be carried out using either alkaline or acid catalysis, but the former is faster. The reaction mechanisms in acidic and alkaline media differ. In acids, condensation takes place at the same time. Hence, hydroxymethylation is carried out industrially in an alkaline or slightly acidic solution.

In hydroxymethylation, a semiaminal bond is formed:

Monohydroxymethylurea

This is cleaved readily, and hydroxymethylation reactions are reversible and establish an equilibrium [32]. Although mono-, di-, and trihydroxymethylurea are formed and isolated easily, tetrahydroxymethylurea is virtually nonexistent in aqueous solution. The complete hydroxymethylation of all amino groups to form hexahydroxymethylmelamine can be carried out readily. The hydroxymethylation of urea is slightly exothermic:

$$H_2N\text{-}CO\text{-}NH_2 + CH_2O \rightleftharpoons H_2N\text{-}CO\text{-}NH\text{-}CH_2OH$$

$$\Delta H = -23\ \text{kJ/mol}$$

The ΔH data given in the literature fluctuate about this value by ± 5 kJ/mol. The enthalpy of hydroxymethylation of melamine, relative to the amount of formaldehyde, is -15 kJ/mol [29], [30].

Reaction rates have been measured frequently, but they are sensitive to many parameters [19], [29].

Industrial processes produce variable mixtures of oligomers with mixed repeat units, so the overall reaction rate is also variable and cannot be defined. Moreover, the important resin properties have not been correlated with the individual reaction rates. In general, the hydroxymethylation rate increases with increased concentration, temperature, and pH. Substituents also have an effect; adjacent electron-withdrawing groups reduce the reaction rate, as do bulky substituents.

5.1.2. Condensation

The condensation is catalyzed by acids. Catalysis by strong alkalis has been described also, but the resulting amino resins are not important industrially [23]. The condensation can take place by the following routes:

Although the presence of methylene compounds in amino resins can be established unambiguously by means of ^{13}C NMR, bis(ureamethylene) ethers can be detected only by an indirect procedure [31]. Carbon-13 NMR spectroscopy permits the elucidation of many of the structures but does not distinguish between the **C** atoms shown in boldface in (**6**) and (**7**), although their third nearest neighbors are different.

This problem also occurs in the case of melamine resins [33].

The methylene bonds between two urea molecules are very stable and can be hydrolyzed only by strong acids at elevated temperatures (see Chap. 8). The condensation reaction is slightly exothermic; the enthalpy is -28 kJ/mol [29]. The stability of the methylene-ether bond is between that of the hydroxymethyl bond and that of the methylene bond.

It is impossible to give a single reaction rate for the condensation process because there are many different starting materials (hydroxymethyl compounds) and many end products (methylene compounds).

The type of solvent also has an effect on the condensation rate [34]. The dependence of the reactivity of hydroxymethyl compounds on the chemical composition of the amino compounds can be interpreted on the basis of several qualitative rules [35].

5.1.3. Principal Components of an Amino Resin Solution

It is possible to identify the most important structural moieties of the oligomers in amino resin solutions by means of ^{1}H and ^{13}C NMR spectroscopy [22], [31], [36].

The hydrates of the formaldehyde oligomers $HO(CH_2O)_nH$, where n is about 5, can be detected along with the following hydroxymethyl structures:

Ethers, such as hydroxymethyl methyl ether, also can be identified in the spectrum by distinguishing the C atoms of the parent alcohol.

Finally, the structures (**8**) and (**9**) and ring compounds, including cyclic ethers of the urone type, also appear.

Asymmetrical **8** Symmetrical **9**

In a typical particle board glue, the ^{13}C NMR spectrum might show, for example, the following distribution of the carbon atoms of the original formaldehyde (mole fractions):

formaldehyde 0.03
hydroxymethyl compounds 0.72
methylene compounds 0.15
cyclic compounds 0.10

5.2. Production Processes

Amino resins usually are prepared in 5 – 20 m^3 batches. However, continuous processes are employed also, particularly for the production of resin glues. The patent literature describes processes where a particular stage is operated continuously while other stages are operated batchwise.

Because the reaction rate and the composition of the end product are influenced by a large number of parameters, the reaction must be controlled carefully. Important reaction parameters are:

1) purity or composition of the starting materials
2) molar ratio in each of the reaction stages
3) type and amount of modifier
4) reactant concentrations
5) the pH value at each stage of the reaction
6) temperature at each stage of the reaction
7) type and concentration of catalyst
8) amount of buffer salt
9) reaction time in each stage

The large number of reaction parameters and resultant adaptations of the process lead to a very extensive body of relevant literature, particularly patent literature. Only the important processes are described here, but a comprehensive review can be found in [1, pp. 101 – 105].

5.2.1. Batchwise Production

The batchwise procedure is the most widely used method for the industrial production of amino resins, but it has the disadvantage of a relatively small production capacity. Nevertheless, this process permits an extensive variety of products and frequent changes of product.

The reactions are carried out in stirred kettles, in two or more stages, at 70 – 100 °C. In the first stage, which is carried out in a slightly acidic to alkaline solution, the principal reaction is hydroxymethylation. In subsequent stages, the condensation is carried out, water is split off, and higher molecular weight products of increasing viscosity are obtained. The duration of the condensation depends on the properties desired in the product. In general, the products are concentrated to 60 – 70 % aqueous solutions by evaporation. The starting materials, urea or melamine, are employed in powder form. Urea also can be used in solution. Formaldehyde is employed as a 37 – 55 % aqueous solution. In a few special cases, formaldehyde is used in the solid form, paraformaldehyde. Finally, it is possible to employ urea – formaldehyde precondensates in concentrations of not more than 80 % by mass of the active ingredients.

Figure 1 shows a diagram of a plant for the batchwise production of aqueous solutions.

Figure 1. Plant for the batchwise production of aqueous amino resin solutions
a) Stirred kettle; b) Raw material feed; c) Reflux condenser; d) Temporary container; e) Pump; f) Vaporizer; g) Container for finished product; h) Condenser; i) Vacuum pump; k) Vessel for condensed vapors; l) Cooler

Aqueous Solutions. The reactor consists of a kettle equipped with heating and cooling devices, a stirrer, inlets for feeding in the raw materials and for measuring devices, a valve at the bottom for emptying the kettle, and a manhole for cleaning.

The material used is mainly stainless steel, material No. St. 1.4541 or St. 1.4571. Internal coils or external, welded-on, semicircular pipes provide for heating with steam or cooling with cold water. Stirring is carried out by means of a powerful unit consisting of disk or anchor stirrers. Nozzles are welded on in order to meter in the raw materials and to permit measurement of the temperature and pH.

When the condensation is complete, the product is evaporated. This is carried out in the stirred kettle, or more economically in a single- or multistage tubular vaporizer, with the pressure reduced to protect the resin. The quality of the resin is then compared to its specifications and it is discharged into a storage container.

The product tanks and the pipelines can be of aluminum or steel because the medium is slightly alkaline. It is advantageous to provide lined iron tanks.

A typical, simple resin glue for particle board production is made as follows [37], [38]: 60 parts (by mass) of solid urea are introduced into 158 parts of a 40 % formaldehyde solution that has been rendered neutral. The mixture is kept at 80 °C for 10 min, during which time hydroxymethylation takes place. The pH is then brought to 4 – 5 by adding a 10 % formic acid solution. The condensation causes the temperature to rise to 97 – 100 °C within a few minutes. This temperature is maintained for about 30 min or until a mixture of 1 part of reaction solution and 5 parts of water gives a white precipitate at 15 °C (sharp endpoint). The reaction mixture is then brought to pH 7 with a 25 % sodium hydroxide solution. This terminates the condensation. A further 16 parts (by mass) of urea are then added, so that the molar ratio of formaldehyde to urea in the end product is 1.65. The resulting solution has a solids content of 51 %. The resin solution is evaporated under reduced pressure to the commercial concentration of 66 %.

This 66 % solution of amino resin forms a milky solution and has a viscosity of about 500 mPa · s (at 20 °C) and a density of 1.290 g/cm^3.

A typical resin for the impregnation of paper webs used in producing decorative laminates can be made as follows [12, p. 258]:

126 parts (by mass) of melamine are introduced into a stirred solution of 120 parts of a 40 % formaldehyde solution and 70 parts of

Figure 2. Plant for the production of amino resin powders by spray drying [18, p. 501]

water at room temperature. The reaction mixture is brought to pH 9 by adding aqueous sodium hydroxide solution and is then heated very rapidly, i.e., in 20 – 30 min for an industrial-scale mixture, to a temperature of 100 °C. After the melamine has dissolved, a process that takes place exothermally, sodium hydroxide solution is added continuously to keep the pH value of the reaction mixture at 8.5 – 8.8 throughout the condensation. Condensation is carried out, with gentle refluxing and stirring, until the reaction mixture is compatible with water when mixed in the ratio 1 : 1.5. This is the case when a sample of the reaction mixture exhibits slight cloudiness when water, at 1.5 times the amount of solution, is added at 20 °C. The reaction solution is then cooled rapidly and brought to pH 9.5 – 10 at room temperature by the addition of sodium hydroxide solution. The resultant impregnating resin solution has a solids content of about 55 % and is usually clear.

Amino Resin Powders. In the production of amino resin powders, an aqueous resin solution is first produced (Fig. 2) and then fed into a spray drier, where it is atomized by a spray disk or nozzle. The resultant droplets are dried in the stream of hot gas produced by heating air indirectly in a heat exchanger or by mixing hot exhaust gas with air. The powder is collected in a tower and in cyclone separators or filters. It passes via a vibrating sieve into a mixing bin and then pours into sacks or drums.

Etherified Products Containing Solvent. Products of this type, which are used as starting materials for making surface coatings, can be produced in a reactor like that described in the production of aqueous solutions of amino resins (Fig. 3). The reactor must be equipped with a sufficiently large heat exchanger to vaporize the mixture of water and excess alcohol, e.g., butanol. Downstream from the heat exchanger is a water separator. The separated aqueous phase still contains from 1 to 2 % formaldehyde and 20 % alcohol and therefore must be worked up. At the appropriate alcohol content, this solvent phase is recycled to the production process.

A butylated melamine – formaldehyde resin for surface coatings can be produced in the following way [11, p. 69]:

60 parts (by mass) of melamine, 60 parts (by mass) of formaldehyde (calculated at 100 %) in the form of a 40 % aqueous solution, and 220 parts (by mass) of butanol are refluxed for 30 min in a stirred kettle equipped for heating. Distillation is then carried out until water no longer evaporates. Then a further 20 – 25 parts (by mass) of anhydrous butanol are distilled.

The mixture is cooled, the resin content is determined, and the concentration is then brought to 50 % with butanol.

5.2.2. Continuous Production

The continuous industrial production of amino resins was begun in order to meet rising demand. The disadvantages of continuous production are that the amount produced per unit time in a particular plant can vary only within relatively narrow limits because prolonged residence under otherwise constant conditions increases the proportion of molecules with high degrees of condensation. Changing product is not simple either. If the plant is not cleaned out beforehand, a product having a composition between the old product and the new will be formed for a time. For this reason, the continuous production process is employed where the variety of products is restricted to a relatively narrow range. On the other hand, continuous procedures give a very uniform product quality.

Figure 3. Plant for the batchwise production of etherified amino resins
a) Raw material feed; b) Stirred kettle; c) Condenser; d) Vacuum pump; e) Separating vessel (water separator); f) Product vessel; g) Pump

The patent literature describes a large number of continuous processes. They differ only in process technology for the product flow. In general, the differences include variations in the temperature, pH, concentration, or modifiers. The process and product flow otherwise remain unchanged. In many cases the publications only describe laboratory- or pilot-scale plants that have not been scaled up for industrial use. Of the continuous processes that have been described, only those with basic differences in type are discussed here.

Aqueous Solutions. The apparatuses employed for the continuous production of aqueous amino resin solutions are tube reactors, stirred kettle cascades, or combinations of the two. The danger of incrustation by highly condensed, insoluble products is greater in the continuous process than in the batch process. In the latter, the residues are dissolved by fresh resin solutions; this is not the case in the continuous process because very little backmixing occurs.

A continuous two-reactor process was described by the Girdler Corp., United States of America, in 1943 [39]. The reactants were mixed thoroughly in the first reactor and heated to about 150 °C under pressure. In the second stage, the solution under pressure was maintained at this temperature and condensation was carried out. The pressure of the reactor was then released, with the result that volatile constituents, especially water, escaped from the resin and the solution cooled.

According to a 1949 patent granted to Sherwood Paints, UK, the reaction is carried out in a packed column [40] and water vapor is expelled by means of a countercurrent gas stream.

A process of Allied Chemical Corp., United States of America (1951), operates in a similar manner and employs a tubular coil as the reactor [41]. The resin solution is subsequently evaporated. Another process of Allied Chemical Corp. is carried out under pressure, using injected steam (1952) [42].

According to an application by Spumalit-Anstalt, Liechtenstein, the starting materials are passed over a solid catalyst (polycarbamide resin) under a pressure of 400 kPa at 140 – 150 °C to form the resin [43].

A process of Rütgerswerke, Germany, from 1955 also uses a fixed-bed catalyst, an ion exchanger [44]. The resins obtained are used as starting materials for making molding compounds.

A Swedish application by Skanska Attifabriken AB from 1955 describes a process in which starting materials are heated separately and then sprayed into a chamber to undergo partial condensation [45]; the reaction is completed in another chamber. The advantage claimed is that none of the final products participates in the initial stages of the condensation.

An application by Du Pont, United States of America, in 1956, describes a continuous process for producing etherified formaldehyde – urea resins [46]. The stepwise reaction takes place in a cascade of two to four stirred kettles. The free alcohols (e.g., butanol, isobutanol, and others) are distilled in the last stage, and some of them are recycled.

In a Meissner process from 1966, the hydroxymethylation stage is carried out continuously and the subsequent condensation stage is operated batchwise [47]. The continuously flowing product stream from the first stage passes through a stirred kettle, which is one of a large number of kettles, so that the product flow need not be interrupted.

Other continuous processes have been worked out by Rheinpreussen AG [48] and the St. Regis Paper Co. [49], but these processes predominantly relate to phenoplasts.

A BASF process (1971) is shown diagrammatically in Figure 4 [50]. The reaction is carried out in a series of three or more stirred kettles. At the beginning of the cascade predominantly hydroxymethylation takes place. Condensation occurs later in the cascade. The reaction is terminated in the last section by the addition of sodium hydroxide solution. The resin solution passes into a temporary container and is subsequently evaporated under reduced pressure in a single- or multi-stage vaporizer. The vapors, containing about 2 % formaldehyde, are worked up and the effluent is discharged for treatment. The end product is cooled and pumped into a tank.

Other cascade processes have been described in applications of SIR, Milano, Italy, (1972) [51] and Montedison (1980) [52].

Finally, mention should be made of the process in which formaldehyde is absorbed directly in urea solutions to produce highly concentrated, formaldehyde-rich solutions that are used as starting materials for glue resins. Examples of conventional commercial products are Kaurit-Konzentrat 244 fl. or 255 fl. (BASF), Formurea 80 (Montedison), and Saruform 80 (Chemische Werke Saar Lothringen).

Stamicarbon [53] and American Cyanamid [54] have described the continuous production of concentrated, formaldehyde-rich melamine – formaldehyde solutions. These too can be used as starting materials for amino resins.

Resins in Powdered Form. Resins in powdered form also can be produced by a continuous procedure if the spray solutions, which in general are produced batchwise, are fed continuously from a temporary container into a spray tower [18].

5.2.3. Production of Special Products and Foams

In addition to impregnating resins, special products include foamed resins and resins for paper auxiliaries, label adhesives, concrete liquefiers, leather auxiliaries, carpet coatings, microcapsules, etc. Because of the relatively small individual amounts and the large variety of products, these resins are produced virtually always in batches. The principle of the production is the same as that for the manufacture of resin glues. The proprietary know-how relates to modifiers and small but important variations in the manner in which the process is carried out.

The foamed resins (→ Foamed Plastics) are an interesting type of amino resin. They are used to produce solid foams, which have a wide variety of applications. The productions of the foamed resin solution and the end product, i.e., the foam, are discussed together.

In 1927, E. C. Bayer discovered that porous, heat-insulating materials are obtained if a foam or a foam-forming substance is added to a glue solution and the mixture is foamed and allowed to harden. In 1933, a process for the production of a foamed urea formaldehyde resin was developed by I. G. Farbenindustrie. In this process, a foaming agent and air were used to produce a primary foam that itself contained the acid, e.g., phosphoric acid, for curing the amino resin. Curing begins after a few seconds and is complete after 12 – 24 h at room temperature. After drying, the foamed urea formaldehyde resins have

Figure 4. Plant for the continuous production of aqueous amino resin solutions [50]
a) Starting material feeds; b) Stirred kettle; c) Reflux condenser; d) Flare; e) Temporary container; f) Pump; g) Vaporizer; h) Product container; i) Cooler; k) Condenser; l) Vacuum pump; m) Container for condensed vapors

bulk densities of 5 – 70 kg/m^3. More than 60 % of the foam is in the form of open cells.

Whereas UF foams previously could be prepared only in factories of fixed location, W. Bauer in 1953 described a transportable apparatus that permitted on-site production of the foam by means of compressed air [55]. A number of other apparatuses subsequently were developed. The state of the art is reported in [56] with respect to the design of foam-producing apparatus and a novel high-performance apparatus of this type is described. The development of foam-producing apparatuses led to much wider applications: soil conditioning in agriculture, heat insulation, sound insulation, filling of mining cavities, carrier material for cleaning fluids, and covering for landfills.

6. Environmental Protection

All necessary measures possible, according to the state of the particular art, must be taken during the production and processing of amino resins to avoid air and water pollution. Regulations constantly become more stringent.

Regulations or recommendations concerning concentration of formaldehyde in rooms are:

Denmark 0.15 mg/m^3
Finland 0.15 mg/m^3
Italy 0.12 mg/m^3
Netherland 0.12 mg/m^3
Sweden 0.48 mg/m^3
Switzerland 0.24 mg/m^3
Germany 0.10 mg/m^3

Effluents [57]. The condensed vapors or effluents from amino resin production may not be introduced into water without biologic treatment. It should be further ensured that these effluents cannot penetrate into ground water.

Waste waters or partially hardened residues inevitably result when machines and containers are cleaned. The amount of wash water or solvent should be kept as small as possible. If the waste water contains predominantly urea or formaldehyde, it can be reused in the production process. Otherwise, it is eliminated, for example, by incineration.

The biologic treatment of industrial effluents from amino resin production is carried out pri-

marily because of the formaldehyde, which is toxic. The usual effluents contain formaldehyde in concentrations that can be degraded readily by bacteria, which are always present. In general, a critical factor in the biologic treatment of any effluent is the concentration in which the various toxic components are present.

Air. The treatment of waste gas by washing with water, catalytic combustion, or thermal combustion is used in industry. The waste gases should be very concentrated to minimize treatment costs.

Solid Wastes. Amino resins can be solidified by hardening them with ammonium chloride or phosphoric acid, or they can be absorbed in sawdust or sand. In this form, they may be deposited in a landfill in accordance with the relevant provisos and legal requirements.

7. Types of Resins and Their Properties

In addition to the simple types of resin that are produced in the largest amounts, i.e., the urea – formaldehyde and melamine – formaldehyde resins, other types of resin with different properties have been developed. These are modifications, i.e., versions of a resin obtained by use of relatively small amounts of additive or by changing the aldehyde or amino component. However, even where the composition is fixed the resin type can be varied by changing the reaction procedure. This leads to different distributions of oligomers or to different substitutions of the repeat units. The distribution of hydroxymethyl groups is the determining feature.

7.1. Urea Resins (UF Resins)

All the urea – formaldehyde condensates [*9011-05-6*] containing the repeat unit **1** (see Chap. 3), from monomolecular product to high molecular weight ones, are useful substances. In the past few years, a number of discoveries have been made concerning the composition of UF resins. Systematic investigations into the process of condensation and the structural composition had long been impossible because of the lack of suitable analytical methods. Industrial development took place largely on an empirical basis. However, using a combination of analytical methods, e.g., ^{1}H NMR spectroscopy, ^{13}C NMR spectroscopy, C, H, N, O elementary analysis, determination of hydroxymethyl groups, and determination of total formaldehyde, it is possible in principle to determine the structural units and their concentrations [22]. However, the relationship between the technical properties of the amino resins or the materials produced from these resins and the distribution of the structural units is still unclear in most cases, so development is still largely empirical.

7.1.1. Pure Urea – Formaldehyde Resins

Important macroscopic parameters are the molar ratio of formaldehyde to urea, the viscosity, and the gelling time. Urea – formaldehyde condensates having a molar formaldehyde : urea ratio of 1 usually give insoluble polymethylene – ureas that do not possess any adhesive properties. If, however, the molar ratio is reduced from a relatively high value gradually or stepwise in the course of the reaction, the resultant resin possesses adhesive properties. These properties improve as the molar ratio increases, but the undesirable release of formaldehyde increases simultaneously.

The highly viscous resin solutions obtainable by prolonged industrial condensation of urea and formaldehyde are low molecular mass products. They contain about six to eight urea units, as can be determined by gel chromatographic [21] and cryoscopic measurements and by end-group determinations. This also applies to the completely insoluble powdered or glassy condensates [58]. During storage, the concentration of methylene groups increases at the expense of the hydroxymethyl groups. The viscosity also increases, initially slowly and virtually linearly, and then, after a critical time, rather steeply. Some or all of the hydroxymethyl groups generally can be blocked by etherification, and the shelf life of the amino resin is thus extended [27], [59], [60]. In principle the same reactions take place when the resin is hardened by the user, but they are substantially more rapid.

However, a residual amount of hydroxymethyl groups remains after hardening [21]. Because they are susceptible to hydrolysis, even the cured urea resins are more water sensitive than the melamine or phenol resins.

The gelling time [11, p. 174] or reactivity of the resin is an important parameter for the user. This time can be determined relatively precisely, and is the time in which the resin changes from a fluid to a virtually immobile solid following the addition of a certain amount of hardener at a particular temperature. The reactivity increases with increasing molar ratio, content of hydroxymethyl groups, and content of free formaldehyde.

7.1.2. Mixed Condensates

Industrial amino resins contain mixtures of various condensates and cocondensates. Amino resin solutions are always polymeric mixtures having various degrees of condensation and differing distributions of functional groups. Resin-forming monomers employed as textile auxiliaries constitute an exception, but these in themselves are not resins. The term mixed condensates is rather loosely applied to those resins which are formed in the condensation of urea and formaldehyde when the reaction is carried out using substances that also form resins with formaldehyde. These are, for example, melamine, phenol, organic acid amides, sulfonamides, and carbamates. Therefore, in the presence of melamine or phenol, it is possible to prepare urea resins with improved strength and swelling properties for the manufacture of particle board, i.e., weather-resistant particle board. Modification with melamine gives resin glues that can be used to produce good-quality particle board even when the molar ratio of formaldehyde to urea is low.

Mixed resins with other resin formers, e.g., acrylic acid, acrylates [61], [62], acrylamide [1, pp. 109] and their derivatives, are also sometimes advantageous. These are also mixtures of polymers, of cocondensates, or of homologous polymers and cocondensates.

7.1.3. Condensation of Urea with Other Aldehydes

Condensation of urea with isobutyraldehyde, acetaldehyde, or crotonaldehyde is carried out industrially to obtain sparingly soluble nitrogen fertilizers, i.e., controlled release fertilizers, rather than resins [63], [64]. The condensation of urea or melamine with glyoxal gives products that can be employed as textile auxiliaries. Products obtained by the subsequent condensation of UF resins with glyoxal (e.g., DMDHEU [*1854-26-8*]) also are used for textile finishing [65], [66].

7.1.4. Resins from Urea Derivatives

Condensation with urea derivatives or substitution products are well known, but these reactions are of industrial importance only for making textile and paper auxiliaries. Reactions with aldehydes can take place depending on the hydrogen atoms still present at the nitrogen, but the ability to undergo condensation decreases sharply with the size and number of substituents.

The reaction of a symmetrically disubstituted urea derivative, e.g., *N,N′*-dimethylurea or dihydroxymethylurea dimethyl ether, with formaldehyde in an acidic medium gives cyclic urea derivatives of the urone type [67, p. 9]:

Dihydroxymethylurone dimethyl ether, bis(methoxymethyl)urone [*7388-44-5*] is used industrially to provide cellulose fabrics with a wrinkle-resistant finish. It has middling reactivity and stability to hydrolysis [68, pp. 164 – 174]. The urones do react with cellulose but form only minor amounts of self-cross-linked resins, such as the urea – formaldehyde compounds.

When S is substituted for O in urea, thiourea is obtained. The latter undergoes all of the principal condensation reactions of urea. In a weakly alkaline medium, *N*-hydroxymethyl compounds and *S*-hydroxymethyl compounds are formed. The tautomeric structure NH_2–C(SH) = NH may be assumed initially for the

latter. The thiourea – formaldehyde condensates are more water resistant than the corresponding urea condensates. Some of the thiourea condensates are assumed to be cyclic compounds [69].

7.1.5. Modified Urea Resins

There is very extensive literature on the possible methods of modifying amino resins [1, pp. 95] and only the most important modifications are discussed here.

Reactions with Alcohols. The hydroxymethyl groups can be etherified with alcohols in an acidic medium [13, pp. 334].

$$-\underset{\underset{H}{|}}{N}-CH_2-OH + ROH \overset{H^+}{\rightleftharpoons} -\underset{\underset{H}{|}}{N}-CH_2OR + H_2O$$

The equilibrium constants for the etherification of monohydroxymethylurea and dihydroxymethylurea with methanol and ethanol have been measured [59]. The enthalpy of reaction, estimated from the temperature dependence of the equilibrium constant, is $\Delta H = -6$ to -8 kJ/mol. The equilibrium constants (K) differ depending on the substitution:

	$K_{30\,°C,\,R=CH_3}$
$H_2N-CO-NH-CH_2OH + ROH \rightleftharpoons H_2N-CO-NH-CH_2OR + H_2O$	0.6
$HOCH_2-HN-CO-NH-CH_2OH + ROH \rightleftharpoons ROCH_2-HN-CO-NH-CH_2OH + H_2O$	7.6
$ROCH_2-HN-CO-NH-CH_2OH + ROH \rightleftharpoons ROCH_2-HN-CO-NH-CH_2OR + H_2O$	2.0

$$K = \frac{[\text{Ether}] \cdot [H_2O]}{[\text{ROH}] \cdot [\text{Hydroxymethyl}]}$$

As the number of C atoms in the alcohol increases, the equilibrium is shifted and the reaction rate reduced so that the etherification becomes more difficult. The ethers of the low-boiling alcohols can be transetherified with higher boiling alcohols by heating the mixture in weakly acidic solution and distilling the more volatile alcohols [13, p. 336].

Frequently only some of the hydroxymethyl groups of resin glues and impregnating resins undergo etherification with monohydric or polyhydric alcohols of less than five carbon atoms. As a result, some of the hydroxymethyl groups are protected against condensation, and the resins have a longer shelf life [1, p. 115], [70], [71]. In the starting materials for surface coatings, 20 – 100 % of the hydroxymethyl groups undergo etherification, depending on the type. The amino resins etherified with butyl groups are the most important for wood coatings, e.g., parquet coating. Where complete etherification takes place, the reaction is carried out using an entraining agent – the alcohol itself, toluene, or xylene – and the water is distilled azeotropically.

Ethers of one- to three-carbon alcohols with low molecular mass hydroxymethyl compounds of urea, ethylene urea (imidazolidinone [*28906-87-8*]), propylene urea (1,3-bis(hydroxymethyl)tetrahydro-2-(1*H*)-pyrimidinone [*65405-39-2*]), and melamine have achieved some importance in the field of textile auxiliaries [3, p. 168], [59], [68]. These compounds are precondensates having relatively low molecular masses, about 600.

Urea resins etherified with butyl groups can be employed as starting materials for making surface coatings. However, when baked alone, they give brittle and water-sensitive films. Therefore they cannot be used alone as binders. In combination with nitrocellulose, or with alkyd, epoxy, or acrylate resins, they give excellent baked finishes.

Reactions with Ammonia and Amines. Amines are very reactive toward hydroxymethyl compounds obtained from urea and formaldehyde. Ammonia reacts with the hydroxymethyl group to form an amino or imino group, eliminating water:

$$\text{-NH-CH}_2\text{OH} + NH_3 \longrightarrow \text{-NH-CH}_2\text{NH}_2 + H_2O$$

The reaction of ammonia with formaldehyde is exothermic ($\Delta H = -57$ kJ/mol) [1, p. 49] and gives hexamethylenetetramine. This reaction has been used industrially to trap formaldehyde

from waste gases, for example, from particle board production [72–74]. The reaction of urea and aldehydes with primary amines gives cyclic compounds (triazines) [75] of the type **10**, where R′ can be hydroxymethyl and its methyl and ethyl ethers.

10

Ammonia, primary or secondary amines, or polyamines containing two or more primary amino groups are used for the production of amino-modified resins [3, p. 206]. They are more stable to water than the unmodified resins produced by a similar procedure.

As shown in the equation above, ammonia and amines can react with the hydroxymethyl groups in urea, in a weakly acidic or alkaline medium, to give *N*-aminomethyl groups. In strongly acidic solution, these eliminate the amine substituents to form condensates. This condensation is similar to that starting with hydroxymethyl groups. Even very highly condensed urea resins are able to bind large amounts of ammonia and amines because a substantial part of the formaldehyde is still present in the form of hydroxymethyl groups. This reaction is utilized industrially, for example, to deodorize resins or particle board [72].

Condensation of the resin molecule with an amine produces a resin that has a cationic character; this increases the resin's affinity for cellulose fibers when it is used as an auxiliary for textiles or paper. These basic urea resins are therefore mainly important because they improve the wet tensile strength of paper.

Reaction with Sulfites. Just as formaldehyde hydrate reacts with a sulfite, so the hydroxymethyl groups of the amino resins react with a hydrogen sulfite or a sulfite to give an aminomethanesulfonate [1, p. 120]:

$$\text{R-NH-CH}_2\text{OH} + [\text{HSO}_3]^- \longrightarrow [\text{R-NH-CH}_2\text{SO}_3]^- + \text{H}_2\text{O}$$

This imparts an anionic character to the resins [3, p. 206]. The pH of the solution controls its sulfite content.

$$[\text{SO}_3\text{H}]^- \rightleftharpoons [\text{SO}_3]^{2-} + \text{H}^+$$

To produce resins of this type, the reaction of, e.g., urea and formaldehyde is begun in a neutral or alkaline medium in order to achieve hydroxymethylation. When the desired degree of conversion has been achieved, condensation is carried out using sulfite or hydrogen sulfite in a slightly acid solution [76]. However, the resin can react with a hydrogen sulfite because many hydroxymethyl groups are still present. Water-insoluble resins can even be rendered soluble by posttreatment with a hydrogen sulfite. Although, like unmodified resins, the amino resins produced using sulfites exhibit an increase in viscosity on aging, they remain water soluble because of their hydrophilic ionic groups.

The anionic resins are of particular industrial importance in the field of water-soluble or water-dispersible adhesives. Other uses include textile auxiliaries [77], paper auxiliaries [78], leather auxiliaries, and deodorants [79] for UF resins [80].

In addition to modification with sulfite, the relevant patents mention many other modifiers, such as aldehydes and triazines. The affinity of the anionic resins for cellulose (which carries a slight negative charge) is lower than that of the cationic resins; therefore, the fibers must be posttreated with aluminum sulfate to fix the resins.

The modification of urea–formaldehyde resin glues with ligninsulfonic acid should be mentioned also [81], [82]. The products are dark resin solutions that have been used from time to time in the woodworking industry. The mechanism involved in the incorporation of the nonuniform lignin is still unclear [1, p. 120]. Lignin contains phenolic groups. Incorporation of the lignin components imparts relatively high water resistance, among other things. The lignins are of different origins and compositions, so that the production process must be adapted empirically to the different lignin varieties. This fact and the dark coloration have prevented more extensive use of lignin wastes from wood pulp production.

7.2. Melamine Resins

7.2.1. Unmodified Melamine Resins

Melamine [*9003-08-1*], like urea, can react with formaldehyde [9, p. 65]. The addition of formaldehyde at the amino group is carried out at pH 9 – 10 and takes place very rapidly. One mole of melamine combines with 6 mol of formaldehyde to form hexahydroxymethylmelamine. Melamine in itself is only slightly soluble even in hot water [9, p. 60]. However, it dissolves readily in aqueous formaldehyde solutions, forming hydroxymethylmelamines. A small part of the melamine remains physically dissolved. When heated, hydroxymethylmelamines undergo cross-linking [9, pp. 66] and form resins that become more insoluble the longer they are heated. Melamine condenses with formaldehyde in acid solution to form hydroxymethyl compounds. This is followed by a more rapid polycondensation, yielding cross-linked products, than in the case of urea – formaldehyde [13, p. 359]. Melamine – formaldehyde resins can be hardened thermally in the absence of a hardener or they can be hardened in the absence of heat, using a very strongly acidic hardener. The hardening processes, as in the case of the urea resins, are not entirely clear. Crosslinking takes place principally via methylene bridges, but it also has been suggested that methylene-ether bridges play a role. The melamine formaldehyde condensates possess good thermal stability, optical properties, and water resistance [13, p. 350].

7.2.2. Modified Melamine Resins

Reaction with Alcohols. Melamine hydroxymethyl compounds can be etherified with alcohols in the same manner as hydroxymethylurea compounds [13, p. 361]. The most important use of the products is as surface-coating resins, but they also are used as textile auxiliaries and even as melamine – urea – formaldehyde resins and impregnating resins. As in the case of the urea resins, etherification is carried out at relatively high temperatures with acid catalysis. Where etherification is carried out to a substantial degree, it is important to remove the water or excess alcohol from the weakly acidic solution, because cross-linking otherwise competes with etherification. The mono- to hexaalkyl ethers of the C_1 to C_4 alcohols can be prepared readily. Good conversions are obtained for higher alcohols only by means of transetherification [83].

Methyl ethers of melamine hydroxymethyl compounds are readily soluble in water even at room temperature and crystallize readily [3, p. 361]. The aqueous solutions of the methyl ethers prepared from higher hydroxymethyl compounds, i.e., those with a higher molar ratio of hydroxymethyl groups, become cloudy on heating and clarify again when cooled. Most of the methyl ethers are soluble not only in water but also in benzene and similar solvents. The products etherified with higher alcohols, e.g., butanol or benzyl alcohol, are water insoluble but are readily soluble in alcohols and some hydrocarbons. In addition to monoalcohols, polyhydric alcohols, e.g., ethylene glycol, glycerol, 3-hydroxymethyl-1,5-pentanediol, pentaerythritol, can be employed as etherification agents. This etherification must be carried out in neutral solution because the competing cross-linking reaction otherwise takes place more rapidly and forms insoluble products.

Like the corresponding urea resins, the etherified melamine – formaldehyde resins used as starting materials for surface coatings are condensates having low molecular masses, 600 – 1400 [84]. These are presumably triazine structures linked via methylene bridges and contain from two to four melamine groups. The ether groups are distributed randomly over the triazine rings.

Reaction with Amines. Amines and aminocarboxylic acids react readily with the hydroxymethyl group of hydroxymethylmelamines in the same way as with urea resins. Modification with amines or amino acids improves the hydrophilic character of the melamine resins. Condensation with amino acids gives alkali-soluble melamine resins that are used to produce impregnating or molding materials [85]. Basic products, which form salts with acids, are obtained by modification with aminoalcohols, e.g., aminoethanol [86], and are used as textile auxiliaries. These products are not of major industrial importance.

Reaction with Hydrogen Sulfite. Melamine resins, like urea resins, react with hydrogen sulfites. Industrially, the cheapest product, i.e., sodium sulfite or sodium hydrogen sulfite, is used, and the reaction is carried out in an acidic or basic medium. The products are readily water-soluble melamine resins that can be precipitated with acids. Hydrogen sulfite-modified melamine – formaldehyde resins are used industrially as concrete liquefiers in the building materials industry. In addition to sulfite, other modifiers described in the patent literature are dithionite and formaldehyde sodium sulfoxylate ($NaHSO_2 \cdot CH_2O$) [87], [88].

Other Modifiers. The modification of hydroxymethylmelamine resins with polyalcohols, sugars, toluenesulfonamides, lactams, nitriles [89–91], acrylates, and polyacrylonitrile [1, pp. 109], [92] is of great importance in the production of impregnating resins. Such modifications improve the large number of laminating properties required and stabilize the resin solution against clouding and excessively rapid increase in viscosity.

Mixed condensates and cocondensates of melamine with other compounds – e.g., phenol, urea, cyanamide, and dicyanodiamide – that react with formaldehyde have also been described in a large number of publications. For example, phenol-modified melamine – urea – formaldehyde resins are used as resin glues for weather-resistant particle board [93], [94]. These resins, too, can be modified in a large variety of ways.

7.3. Urethane Resins

Condensation of a urethane (carbamate) of the formula $H_2N–COOR$ with an aldehyde gives a distinct compound or a resin, depending on the production conditions [8, p. 220], [13, p. 371]. In an alkaline medium, carbamates react with formaldehyde to give hydroxymethyl compounds that split up into the starting materials at higher temperatures. In an acidic medium, they cross-link to form methylene bridges and produce resins that are used to manufacture molding materials. A patent has been applied for regarding the use of urethane resins derived from long-chain aliphatic alcohols as plasticizers [3, p. 220]. Urethane – urea – formaldehyde mixed resins have been described also. The reaction of cyanuric acid with polyhydric alcohols and formaldehyde gives resins that can be used as paper and textile auxiliaries and as starting materials for surface coatings.

In another procedure, urea is converted to the appropriate carbamate by heating in the presence of an alcohol and eliminating ammonia. The subsequent reaction with formaldehyde and cross-linking are carried out as described above [13, p. 374]. The resultant highly viscous solutions can be used as label adhesives and for the adhesive bonding of cardboard boxes.

The properties of urethane resins vary depending on the components and method of production. They range from oily to brittle depending on the degree of condensation. Lower aliphatic and cycloaliphatic alcohols yield hard resins, whereas higher alcohols give waxlike resins.

7.4. Cyanamide and Dicyanodiamide Resins

Cyanamide and dicyanodiamide react with formaldehyde both in acid and in alkaline media [8, p. 199]. Cyanamide reacts with an equimolar amount of formaldehyde at pH 6 – 7 to give a white precipitate, which loses water to form a crystalline compound. In general, cyanamide and dicyanodiamide are used as modifiers [1, pp. 118], [13, pp. 382]. Cyanamide – formaldehyde and dicyanodiamide – formaldehyde resins have been used as mixed resins for starting materials in making molding compositions, as dyeing and tanning auxiliaries, for textile finishing, and for preserving urea – formaldehyde foams.

7.5. Sulfonamide Resins

The most commonly used basic component for this type of resins is *p*-toluenesulfonamide:

With formaldehyde, *p*-toluenesulfonamide forms resins that are fusible but not curable, whereas disulfonamides or amides possessing

other groups capable of condensation give insoluble products that are infusible [95]. The special properties of *p*-toluenesulfonamide resins include compatibility with cellulose surface coatings, pale natural color (in contrast to that of phenol resins), and low tendency to yellow.

Only the *p*-toluenesulfonamide – formaldehyde condensates have become important industrially, and these only as cocondensates or modifiers. Only the combinations with urea – melamine resins, phenol resins, and phthalate resins are of importance [96]. They also are added to melamine – formaldehyde impregnating resins as plasticizers in amounts of 3 – 8 % [1, pp. 109].

7.6. Aniline Resins

Aniline resins include the condensates of formaldehyde with aromatic amines, such as aniline [*25214-70-4*], toluidines, xylidines, naphthylamines, and phenylenediamines [13, pp. 192].

In alkaline solution, the first stage, i.e., hydroxymethylation, leads to a simple condensate:

Condensation to give a cyclic product has been reported also.

The reaction with formaldehyde in an acid medium gives resins in which methylene groups link the aromatic rings directly, as in the case of the phenoplasts (→ Phenolic Resins). The para position is activated by salt formation at the amino group, so formaldehyde can add at this position to form *p*-aminobenzyl alcohol.

Polymer chains are formed and water is eliminated in this process. In the presence of an excess of formaldehyde, three-dimensional networks also form.

The amino groups have a directing function, so tertiary aromatic amines also can form resins. Unlike the phenol resins, aniline resins do not harden further. The aniline resins are therefore thermoplasts in contrast to the resins discussed above, which are duroplasts. The aniline resins are not very important industrially. They have been used in small amounts in the production of molding materials [1, p. 120] and ion-exchange resins and, because of their high resistance to tracking currents, they have been mixed with epoxy resins and used for wire enamels and insulating coatings [97].

8. Analysis

Analysis, insofar as it is used for product control during production, storage, and use, amounts to testing various types of resins for characteristic parameters or selected specifications. Complete elucidation of the chemical structure, including the sizes and amounts of the oligomers, would entail an unacceptably great expense.

Characterization of the products usually includes the following determinations [11, pp. 171], [98–100]:

density in g/cm^3 (in the case of foams, in kg/m^3)
solids content in % by mass
viscosity in mPa · s, usually at 20 °C
free formaldehyde
total formaldehyde
free urea
total urea
melamine
methoxy content
ash content (incombustible modifiers)

The urea – formaldehyde or amino groups – formaldehyde molar ratio is calculated from the analytical data.

Further tests may be employed if special properties are required of the resins. The development of novel products and applications increases the need for analytical effort.

Solids Content. The determination of the solids content in resin solutions is a determination of

the dry matter content. The value is useful only for comparison. It is determined by evaporating the volatile components at 100 – 130 °C over a fixed period of time. This procedure removes not only the water present as a solvent and the free formaldehyde, but also the water and formaldehyde formed during the drying process in the condensation. Therefore the dry matter content is by no means to be equated with the active ingredient content. More exact data are obtained by the determination of water by the Karl Fischer method [101], by freeze drying, or, in organic solvents, by the Aufhauser method. In industry, however, the water content is estimated by the drying method detailed above because this method is simple and quick.

Formaldehyde [102–104]. The free formaldehyde can be determined directly and the total formaldehyde can be determined after the product has been hydrolyzed completely. The hydroxymethyl content can be determined by hydrolysis under relatively mild conditions. The formaldehyde bonded in the form of methylene groups is calculated by difference.

Urea. The total urea can be determined by hydrolysis and the Kjeldahl procedure. The free urea is degraded to ammonia by the enzyme urease [105]. If no other form of nitrogen is present in the resin, the urea content can be calculated from the nitrogen content, which is determined by combustion analysis.

Melamine in amino resins is determined by hydrolysis of the product under mild conditions followed by titration with perchloric acid. Resins having a low degree of condensation can be titrated directly using a computerized automatic apparatus.

The *molar ratio* of urea to formaldehyde can be calculated from the total content of formaldehyde. This ratio provides information on the formaldehyde elimination to be expected.

Methanol is generally present in the form of methoxy groups bonded to hydroxymethyl groups via an ether bond; it is determined by the Zeisel's procedure.

Other components are important, particularly where the resins are used as paper or textile auxiliaries or as starting materials for making surface coatings. Some of these are maleic acid, glyoxal, phenol, and amines and sulfites. The methods of determination are discussed in textbooks on analysis or, for example, in specific articles. These substances are not determined during routine product control.

For research and development purposes, paper chromatography, thin-layer chromatography [106], column chromatography [107], gel permeation chromatography, ^{13}C NMR spectroscopy [22], [31], [36], ^{15}N NMR spectroscopy [119], ^{1}H NMR spectroscopy (using dimethylsulfoxide as the solvent) [31], [108], and infrared spectroscopy are used.

9. Storage and Shipment

Aqueous or alcoholic solutions of amino resins are stored in steel tanks with or without internal epoxide coatings, in stainless steel tanks, or in containers made of fiberglass-reinforced polyester resin. Temperatures above 20 – 25 °C must be avoided because they bring on rapid condensation, which increases the viscosity and soon renders the resin unprocessible. Rotary pumps or – in the case of highly viscous liquids – positive-displacement pumps, e.g., gear pumps, are employed.

Powdered amino resins are packaged in airtight, plastic-lined paper sacks that are sealed against moisture. Certain types of paper bags can withstand tropical climates. Under high pressure, the materials may solidify. Spilled product is taken to a waste dump.

Liquid resin loads of up to about 250 kg are dispatched in small polyethylene barrels, whereas greater loads, up to about 1 t, are dispatched in polyethylene containers encased in sheet metal. Larger amounts are transported in containers, railroad tank cars, tank trucks, or marine tankers. Amino resins must be disposed of if they are damaged or become unstable during transport in tanks.

The relevant regulations governing the disposal of amino resins differ from country to country and even within some countries. A common feature of all the regulations, however, is that the resin must be hardened by the addition of acid curing agents and must be delivered to a licensed landfill. Where leakage occurs during transport, it is advisable to absorb the resin solution with any appropriate agent that is available (e.g., sand or sawdust) and then to deliver the resulting material for incineration. In the Federal Republic of Germany, amino resins are not

included among substances regarded as endangering water.

10. Uses

The properties of amino resins have been adapted by industry to a very large number of applications. New uses are being developed constantly and any list is bound to be incomplete.

Uses include the following: adhesives; impregnating resins; molding materials; starting materials for making surface coatings; auxiliaries for paper, textiles, leather, and flotation; strengtheners for building materials; concrete liquefiers; binders for glass fibers and foundry sand casting; fire lighters; emery papers; flame retardant coatings; flameproofed combustible items; foamed resins for many purposes; grinding wheels; ion-exchange resins; sewage flocculants; and microcapsule production.

The largest amount of amino resins is consumed by the woodworking industry. These resins, along with the phenol resins, have largely replaced the natural glues based on proteins (glutin, casein, soybean, and blood albumin glues). Impregnating resins are used as resin glues in the particle board, plywood, and furniture industries. Impregnating resins also are used to impregnate papers for decorative laminates and for coating wood particle board.

Resin Glues for the Woodworking Industry. The amino resins used as glues in the woodworking industry are available commercially predominantly in the form of 55 – 70 % aqueous solutions or as solids, for example, powders. The powder resins entail lower transport costs but are more expensive because of the costs involved in drying them and must be dissolved by the user. Whereas the powder resins have shelf lives of 1 year or longer if stored correctly, the liquid products, depending on the type, have shelf lives of only 2 – 6 months. During this period the viscosity remains within limits that permit the resin to be pumped with a conventional pump. The amino resins are more or less stable intermediates; condensation is completed by the addition of a curing agent and/or by heat treatment. A curing agent, e.g., ammonium chloride, is virtually always required for the urea resins, whereas melamine resins can be cured at 120 °C. Compared to the melamine or phenol resin glues, the particle board made from urea resin glue has lower water resistance and is not resistant to boiling. If these properties are required, melamine resin glues or mixed condensates of formaldehyde, urea, melamine, and/or phenol are employed.

In addition to water resistance, the tendency to release formaldehyde is very important. If a low level of formaldehyde release is desired, the formaldehyde content of the resin glue must be correspondingly low. In some countries the glue must receive the approval of the authorities.

Over the past few years, MDF (medium-density fiberboard) resins have become increasingly important. The MDF resins are pure or melamine-modified urea – formaldehyde resins that have a low viscosity, about 200 mPa · s. Other modifiers may be used also. Medium-density fiberboard is used in the production of furniture with structured surfaces [1, pp. 179], [109, pp. 266 – 275].

From an economic point of view, the urea resins are the most important amino resin glues because they are inexpensive and possess technical properties adequate for most purposes.

The main use is in the production of wood particle board. These resins also play an important role as glues for plywood and blockboard and for furniture construction. The gluing of load-bearing wood components and shutter panels and the production of shaped articles are further examples of the large variety of uses of amino resin wood glues.

Impregnating Resins. Urea – formaldehyde or melamine – formaldehyde impregnating resins are used to treat papers for decorative purposes. The resins themselves are brittle products and it may be necessary to modify them with a plasticizer. Because of their good properties, i.e., hardness, abrasion resistance, scratch resistance, and stability to light, the amino resins are particularly suitable for this purpose. The impregnated papers are used either to produce decorative laminates or for coating wood particle board. Papers impregnated with melamine resin are more heat stable than those impregnated with urea resin [110].

The paper webs impregnated with the amino resin are dried in a furnace at 70 – 200 °C and

are stored under air-conditioning until they are used.

Table 1. Trade names of amino resins used as resin glues and impregnating resins

Supplier	Urea resins	Melamine resins
Nobel Hoechst Chim. France	Nobelamine	Nobelamine
Société Chimique des Charbonnages S.A. CdF-Chimie France	Pressamine	Pressamine
BP Chemicals UK	Cellobond	–
Montedison Italy	Xylocolla	–
Società Italiana Resine SIR Italy	Sirit	–

Resart FRG	–	Resart
Südwestchemie FRG	Supraplast	Supraplast

Various types of amino resin-impregnated papers are required for decorative laminates. The most important are papers that impart a decorative pattern to the board which itself consists of several layers of phenol resin-impregnated kraft paper.

Ground films and decorative films are likewise amino resin-impregnated papers and are used in the same way as wood veneers in the furniture industry. These films generally are produced from urea resins and to a certain extent also from melamine – urea resin mixtures.

Molding Materials. Molding materials consist of a filler, e.g., cellulose or sawdust, and a binder, which can be a urea resin or a melamine resin. The molding materials obtained from melamine resins are superior to those obtained from urea resins because of their better hardening properties, higher mechanical strength, and greater resistance to tracking currents and moisture [3, pp. 68 – 100].

The molding materials are employed for objects in daily use; e.g., white electrical plugs, switches, covers, telephone accessories, and buttons are made from urea resin. Melamine resin is used for camping, hospital, and canteen tableware, and for junction boxes and insulating com ponents. Mixed resins that combine some of the properties of the individual resins are also used.

The most important trade names of amino resins used as resin glues and impregnating resins are given in Table 1.

Raw Materials for Surface Coatings. Pure amino resins are not very useful as surface coatings. The majority of the commercially available amino resins used as starting materials for surface coatings are etherified with butanol or isobutanol and dissolved therein [3, pp. 124 – 148]. Special brands are also modified with methanol, ethanol, or propanols.

Because the surface coatings obtained using amino resins are too brittle, these resins cannot be used alone as binders. However, they are very useful in combination with other binders. Urea resins and melamine resins are the most important cross-linking components for alkyd resins.

Physically drying finishes are obtained by adding amino resins to nitrocellulose finishes. The addition of these resins improves the hardness, body, and stability to light. The principal field of use is in furniture finishing.

Table 2. Trade names of amino resins used as surface coating resins

Supplier	Urea resins	Melamine resins
Vianova Austria	Viamin	Viamin
UCB Belgium	–	Synkamine
Syntova France	Syntamine	Syntamine
British Industrial Plastics (BIP Chemicals) UK	–	Beetle

Hoechst FRG	–	Maprenal
Jäger FRG	Jägamin	Jägamin
Stickstoffwerk Piesteritz FRG	Piadurol	Meladurol

Acid-curable finishes are obtained by adding alkyd resins or saturated polyester resins. These finishes can be hardened by adding an acid, e.g., hydrochloric acid, *p*-toluenesulfonic acid, or a phosphoric acid derivative, at an elevated temperature. The resulting coatings are very hard and resistant to scratches, solvents, and the effects of light [3, p. 130]. Urea resins are more important than melamine resins, particularly in furniture finishing and parquet sealing.

Coatings that can be cross-linked by heat treatment alone are obtained by combining amino resins with alkyd resins, saturated polyester resins, heat-curable acrylate resins, or epoxy resins. Because of their good mechanical properties, their gloss, and their resistance, these baked finishes are extremely important in industrial metal finishing, for example, for automobile bodywork, household appliances, metal furniture, and containers [111, p. 177].

Because they are etherified and essentially free of water, the amino resins used in the surface-coating industry have shelf lives of from 6 months to several years at room temperature. They are dispatched in plain or galvanized sheet metal containers. Only stainless steel or aluminum tanks are used for transport by tanker trucks and railroad tank cars.

The most important trade names of urea and melamine resins used as starting materials for surface coatings are summarized in Table 2.

Paper Auxiliaries. In the paper industry, amino resins are used to increase the dry tensile strength and especially the wet tensile strength of the product [3, pp. 205 – 209], [112], [113]. In contrast to the procedure followed in the textile industry (see Textile Auxiliaries below), the resin components are added to the paper stock before condensation. They are adsorbed onto the fiber and then undergo condensation in an acid medium. The maximum strength of the paper is reached only after a maturing period of 2 – 4 weeks. Based on the fiber, 1 – 5 wt% of resin is sufficient to achieve good wet strength. The amino resins also are used for the surface finishing of papers. They impart water resistance to starch-containing paper-coating compositions.

The urea resins, which constitute the most important group, are generally hydroxymethyl compounds that have been modified by the addition of amines to give them a cationic character

or by the addition of sulfites to provide an anionic character. After modification, these compounds are subjected to a condensation reaction in an acid medium. The resultant ionic resins are water soluble. The ionic character also enables them to be adsorbed onto anionic paper pulp, but anionic resins must be used with aluminum sulfate [112, p. 43].

Melamine resins also are important to the wet strength of paper. In the absence of other modifiers, they react with acids to form strongly acid cationic colloids that are stabilized by an electric charge and consist of partially condensed hydroxymethyl melamines. Melamine resins modified with aminocaproic acid are also suitable substitutes, either alone or in combination with other polymers, for some or all of the colophony soaps used in the internal sizing of paper [112, p. 42].

A further field of use is the production of moisture-resistant starch pastes for the adhesive bonding of corrugated board [114].

Trade names for aminoplasts used as paper auxiliaries are summarized in Table 3.

Table 3. Amino resins used as paper auxiliaries

Supplier	Resin
Rousselot France	Resin
British Industrial Plastics (BIP Chemicals) UK	Beetle Resin
Mitsui Toatsu Chemical Japan	Uramin

BASF FRG	Urecoll
Hoechst FRG	Madurit

Textile Auxiliaries. The textile auxiliaries based on derivatives of urea, melamine, and formaldehyde [3, pp. 166–181] are predominantly monomeric, and therefore should not be regarded as resins. They contain only unavoidable, small, random amounts of higher condensates. The molecules react with the primary hydroxyl groups of the cellulose on contact with the cellulose fibers. The relatively weak hydrogen bridges of the cellulose molecules are thereby supplemented by additional, stronger covalent bonds. Self-condensation takes place on the surface of synthetic fibers, which do not react with the "amino resin" monomers. This type of auxiliary is discussed here, as are others that stiffen the finish of synthetic fabrics.

The pure urea–formaldehyde adducts, mono- and dihydroxymethylurea, are water soluble and crystallize readily. In crystalline form, they possess the largest share of the market for easy-care and wrinkle-resistant finishes for cellulose textiles and mixtures of cellulose fibers with synthetics and wool. The pastes also consist principally of these basic substances, but some of them are etherified with lower alcohols and exhibit a minor amount of condensation. They are therefore used to provide wrinkle-resistant and wash-and-wear finishes as well as stiffened finishes on synthetic fabrics. The fabrics treated in this manner possess improved wash resistance. Hydroxymethyl compounds of urea that exhibit a high degree of condensation and possess a high concentration of ether groups are used to produce highly elastic stiffening effects and good wash resistance in cellulose fabrics. Because of the relatively low concentration of "amino resin" monomers (about 1 mol of resin per kg of cellulose), cross-linking between the cellulose groups is strongly favored over self-cross-linking. A disadvantage of this class of products is the relatively low stability of the acid treatment liquors in the bath, where condensation can take place easily between the hydroxymethylurea molecules.

An important group is constituted by hydroxymethyl compounds of cyclic urea derivatives; examples are dihydroxymethylethylene urea (**11**), dihydroxymethylpropylene urea (**12**), and dihydroxymethylurone (**13**).

Acyclic compounds, such as various alkyl carbamates, are also typical finishing agents. In contrast to the pure urea–formaldehyde compounds, these exhibit little tendency to form self-cross-linked resins and react predominantly with

11

12

13

cellulose to cross-link the fibers. The other advantages, over and above the mechanical properties, are resistance to chlorinated water, lightfastness, and shade constancy. These are closely related to the chemical structure and the resistance of the C–N and N–O bonds to hydrolysis.

Table 4. Amino resins used as textile auxiliaries

Supplier	Resin
PCUK France	Diamonine
Dai Nippon Ink and Chemicals Japan	Beckamin
Mitsui Toatsu Chemical Japan	Uramin
Sumitomo Chemical Japan	Sumitex Resin
Sandoz Switzerland	Finish
Monsanto USA	Resloom
Sun Chemical USA	Permafresh

Ciba-Geigy/Pfersee FRG	Knittex Lyofix
Henkel FRG	Stabitex
Hoechst FRG	Arkofix
Hoechst FRG	Cassurit
Thor-Chemie FRG	Quecodur

Hydroxymethyl melamine derivatives and their ethers are of some importance for providing high-grade finishes, i.e., embossed finishes, Schreiner finishes, chintz finishes, and plisse finishes, but they have largely been replaced by the reactant types. The finishes obtained using hydroxymethylmelamines are more wash resistant than those made with hydroxymethylureas. Hydroxymethylmelamine compounds are preferred for embossed finishes (Everglaze) where the fabric can be damaged mechanically.

The most important trade names of the textile auxiliaries based on amino resins are summarized in Table 4.

Table 5. Trade names of amino resins used as leather auxiliaries

Supplier	Resin
Hodgson UK	Neosyn
BASF FRG	Relugan
Bayer FRG	Retingan
Henkel FRG	Drasil
Chemtan USA	Chemtan

Leather Auxiliaries. Resin retannage of chrome-tanned leather is carried out using hydroxymethyl compounds of urea, thiourea, melamine, dicyanodiamide, and ethers of these [3, p. 211], [80]. Aqueous solutions of the resins should penetrate the hide before condensation begins. The acid condensation catalyst (pH 3.9 – 4.5) should not reduce the period of activity of the tanning liquor or damage the hide. As in the case of the paper auxiliaries, the resins are rendered cationic using amines or anionic by means of a bisulfite. The anionic resins based on melamine or dicyanodiamide make leather very strong and supple and leave the color unchanged. The hydroxymethyl groups react with the active groups of the collagen fiber, which has a high content of glycine, proline, and oxyproline.

The trade names of a few leather auxiliaries are given in Table 5.

Other Uses of Amino Resins. The number of possible uses is increasing constantly. The uses listed at the beginning of this section are summarized with the appropriate references in Table 6.

The importance of many uses, e.g., flameproofing agents, has declined greatly. Some applications, e.g., casting resins, have proved unsatisfactory in practice, whereas others are only at the development stage and their industrial suitability cannot yet be assessed.

Table 6. Uses for amino resins

Application	Resin and use	References
Binders for glass fiber webs	Reinforcing glass fibers in webs by means of urea resins	[9, pp. 201, 214]
Foams	Soil conditioning, covering landfills, heat insulation, lining tunnels in mines (→ Foamed Plastics)	[115], [1, pp. 196], [3, p. 161]
Foundry sand binders	Binders for sand-casting in the foundry industry; casting molds and cores; modification with furfuryl alcohol	[3, pp. 122]
Concrete liquefiers and auxiliaries for building materials	Sulfite-modified melamine resins	[87], [88]
Flame-proofing agents	Flame-proofing wood by means of amino resins containing phosphorus, boron, bromine, etc.	[1, p. 206], [3, p. 215]
Ion-exchange resins	Melamine-formaldehyde condensates modified with amines Used for recovering silver from photographic effluents	[3, p. 225]
Coatings for abrasive papers	Urea – formaldehyde – furfuryl alcohol condensates for imparting water-resistance	[3, p. 226]
Wood preservatives	Melamine – formaldehyde condensates impart good aging resistance; no shrinkage; no seasoning cracks	[3, p. 227]
Microcapsules	Urea – formaldehyde resins	[1, p. 289], [116]
Firelighters	Emulsion of urea – formaldehyde resin with a liquid fuel and hardeners is processed to give small moldings. Lighting oil-fired furnaces, charcoal grills, etc.	[117]
Sewage flocculants	Urea – formaldehyde resins cause flocculation	[118]

Table 7. Production of amino resins in the OECD countries

Year	Production (10^6 tons)
1969	1.95
1970	2.03
1971	2.20
1972	2.55
1973	3.13
1974	2.79
1975	2.47
1976	2.79
1977	2.94
1978	3.09
1979	3.33
1980	3.14
1981	3.01
1982	2.69
1983	2.66

Comments: The figures for 1974 to 1976 and for 1979 exclude Portugal. The figures include the phenol resins produced in the Federal Republic of Germany. However, this qualification does not greatly change the above figures for world production of amino resins.

11. Economic Aspects

Amino resins have become increasingly important since World War II. The OECD statistics "The chemical industry" and the production statistics of the Federal Statistics Office of the Federal Republic of Germany refer the production for the OECD countries shown in Table 7.

The figures for Europe, USA and Japan are given in Table 8.

The production of particle board, which consumes the largest amount of amino resins in the Federal Republic of Germany, reached a high level by the late 1970s but diminished thereafter.

Table 8. Production of amino resins for Europe, USA and Japan

	Production in 10^3 tons					
	1978	1979	1980	1981	1982	1983

Abstract

The article contains sections titled:

1. Occurrence and History
2. Physical Properties
3. Chemical Properties
4. Production
4.1. Historical Development
4.2. Thermodynamic Data
4.3. Ammonia Synthesis Reaction
4.3.1. General Aspects
4.3.2. Catalyst Surface and Reaction Mechanism
4.3.3. Kinetics
4.4. Catalysts
4.4.1. Classical Iron Catalysts
4.4.1.1. Composition
4.4.1.2. Particle Size and Shape
4.4.1.3. Catalyst-Precursor Manufacture
4.4.1.4. Catalyst Reduction
4.4.1.5. Catalyst Poisons
4.4.2. Other Catalysts
4.4.2.1. General Aspects
4.4.2.2. Metals with Catalytic Potential
4.4.2.3. Commercial Ruthenium Catalysts
4.5. Process Steps of Ammonia Production
4.5.1. Synthesis Gas Production
4.5.1.1. Feedstock Pretreatment and Raw Gas Production
4.5.1.2. Carbon Monoxide Shift Conversion
4.5.1.3. Gas Purification
4.5.2. Compression
4.5.3. Ammonia Synthesis
4.5.3.1. Synthesis Loop Configurations
4.5.3.2. Formation of Ammonia in the Converter
4.5.3.3. Waste-Heat Utilization and Cooling
4.5.3.4. Ammonia Recovery from the Ammonia Synthesis Loop
4.5.3.5. Inert-Gas and Purge-Gas Management
4.5.3.6. Influence of Pressure and Other Variables of the Synthesis Loop
4.5.3.7. Example of an Industrial Synthesis Loop
4.6. Complete Ammonia Production Plants
4.6.1. Steam Reforming Ammonia Plants
4.6.1.1. The Basic Concept of Single-Train Plants
4.6.1.2. Further Developments
4.6.1.3. Minimum Energy Requirement for Steam Reforming Processes
4.6.1.4. Commercial Steam Reforming Ammonia Processes
4.6.1.4.1. Advanced Conventional Processes
4.6.1.4.2. Processes with Reduced Primary Reformer Firing
4.6.1.4.3. Processes Without a Fired Primary Reformer (Exchanger Reformer)
4.6.1.4.4. Processes Without a Secondary Reformer (Nitrogen from Air Separation)
4.6.2. Ammonia Plants based on Partial Oxidation
4.6.2.1. Ammonia Plants Based on Heavy Hydrocarbons
4.6.2.2. Ammonia Plants Using Coal as Feedstock
4.6.3. Waste-Heat Boilers
4.6.4. Single-Train Capacity – Mega Ammonia Plants
4.7. Modernization of Older Plants (Revamping)
4.8. Material Considerations for Equipment Fabrication
5. Storage and Shipping
5.1. Storage
5.1.1. Pressure Storage
5.1.2. Low-Temperature Storage
5.1.3. Underground Storage

5.1.4. Storage of Aqueous Ammonia
5.2. Transportation
6. Quality Specifications and Analysis
7. Environmental, Safety, and Health Aspects
7.1. Environmental Aspects of Ammonia Production and Handling
7.2. Safety Features
7.3. Health Aspects and Toxicity of Ammonia
8. Uses
9. Economic Aspects
10. Future Perspectives

1. Occurrence and History

Occurrence. Ammonia, NH_3, occurs in nature almost exclusively in the form of ammonium salts. Natural formation of ammonia is primarily by decomposition of nitrogen-containing organic materials or through volcanic activity. Ammonium chloride can deposit at the edges of smoldering, exposed coal beds, as observed in Persia before 900 A. D. Similar deposits can be found at volcanoes, for example, Vesuvius or Etna, in Italy. Ammonia and its oxidation products, which combine to form ammonium nitrate and nitrite, are produced from nitrogen and water vapor through electrical discharges in the atmosphere. These ammonium salts, as well as those arising from industrial and automotive exhausts, supply significant quantities of the nitrogen needed by growing plants when eventually deposited on the earth's surface. Ammonia and its salts are also byproducts of commercial processing (gasification, coking) of fossil fuels such as coal, lignite, and peat (see Fig. 1).

Figure 1. The nitrogen cycle

History. The name ammonia is derived from “sal ammoniacum” (Oasis Ammon in Egypt, today Siwa). Sal ammoniac was known to the ancient Egyptians; the Arabs were aware of ammonium carbonate. Free ammonia was prepared for the first time in 1774 by J. B. PRIESTLEY. In 1784, C. L. BERTHOLLET recognized that ammonia was composed of the elements nitrogen and hydrogen. W. HENRY, in 1809, determined the volumetric ratio of the elements as 1 : 3, corresponding to the chemical formula NH_3.

Following the discovery of the nature and value of mineral fertilization by LIEBIG in 1840, nitrogen compounds were used in increasing quantities as an ingredient of mineral fertilizers. At the end of the last century ammonia was recovered in coke oven plants and gas works as a byproduct of the destructive distillation of coal. The produced ammonium sulfate was used as fertilizer. Another nitrogen fertilizer was calcium cyanamide which was manufactured by the Frank – Caro process from 1898 onwards. Since both sources of nitrogen were limited in quantity they did not suffice for fertilization. Therefore, it was necessary to use saltpeter from natural deposits in Chile. In 1913, the first Haber – Bosch plant went on stream, representing the first commercial synthesis of ammonia from the elements. Subsequently, other ammonia plants were started up, and synthetic ammonia and/or its derivatives soon replaced Chile saltpeter. Today ammonia is a commodity product of the chemical industry. World production capacity in 2005 exceeded 168 × 10^6 t ammonia.

2. Physical Properties

Molecular Properties. Corresponding to its nuclear charge number, the nitrogen atom possesses seven shell electrons. One electron pair is in the ground state 1 *s* (K shell), and five electrons are distributed over the four orbitals with the principal quantum number 2 (L shell). Of these, one electron pair occupies the 2 *s* level and three unpaired electrons, respectively, a half of the remaining three levels, 2 p_x, 2 p_y, 2 p_z. The unpaired electrons can enter into electron-pair bonds with the 1*s* electron of three hydrogen atoms. Thus, the three half-occupied orbitals of the L shell become about fully occupied (formation of an octet of the neon type in accordance with the octet theory of Lewis – Langmuir).

The nitrogen atom is at the apex of a pyramid above the plane of the three hydrogen atoms, which are arranged in an equilateral triangle. The H-N-H bond angle is about 107° [7]. Although covalent, the nitrogen – hydrogen bonds have a polar contribution because of the stronger electronegativity of nitrogen relative to hydrogen. Because of polarization of the bonds and the unsymmetrical molecular arrangement, the ammonia molecule has a considerable dipole moment, 1.5 D [8].

As the ammonia molecule possesses the same electron configuration as water (isosterism) and similar bond angles (water vapor bond angle 105°, dipole moment 1.84 D), ammonia and water behave similarly in many reactions. Ammonia and water are diamagnetic. The dielectric constant of liquid ammonia is about 15 and greater than that of most condensed gases; therefore, liquid ammonia has a considerable ability to dissolve many substances. The ammonia molecule, with its free electron pair, can combine with a proton.

In the resulting ammonium ion, the nitrogen atom is situated in the middle of a tetrahedron whose corners are occupied by hydrogen atoms. The four hydrogen atoms are equivalent in their behavior. According to LINUS PAULING, the positive excess charge is distributed about equally over all five atoms.

Compilations of Physical Data. The results of comprehensive investigations of the physical properties of ammonia have been published in [9] and [12]. Both papers provide numerous equations for physical properties derived from published data, the laws of thermodynamics, and statistical evaluation. These equations are supplemented by lists and tables of thermodynamic quantities and an extensive collection of literature references.

Moreover, data on physical properties and the complex systems important in synthesis may be found in [13-16], and of course, in the well-known tabulations *Landolt-Börnstein* [17] and *Handbuch der Kältetechnik* [18], among others. The most important physical data are compiled in Table 1.

Table 1. Properties of ammonia

M_r	17.0312

Molecular volume (at 0 °C, 101.3 kPa)	22.08 L/mol
Specific gas constant *R*	0.48818 kPa m^3 kg^{-1} K^{-1}
Liquid density (at 0 °C, 101.3 kPa)	0.6386 g/cm^3
Gas density (at 0 °C, 101.3 kPa)	0.7714 g/L
Liquid density (at –33.43 °C, 101.3 kPa)	0.682 g/cm^3
Gas density (at –33.43 °C, 101.3 kPa)	0.888 g/L
Critical pressure	11.28 MPa
Critical temperature	132.4 °C
Critical density	0.235 g/cm^3
Critical volume	4.225 cm^3/g
Critical compressibility	0.242
Critical thermal conductivity	0.522 kJ K^{-1} h^{-1} m^{-1}
Critical viscosity	23.90×10^{-3} mPa · s
Melting point (triple point)	–77.71 °C
Heat of fusion (at 101.3 kPa)	332.3 kJ/kg
Vapor pressure (triple point)	6.077 kPa
Boiling point (at 101.3 kPa)	–33.43 °C
Heat of vaporization (at 101.3 kPa)	1370 kJ/kg
Standard enthalpy of formation (gas at 25 °C)	–46.22 kJ/mol
Standard entropy (gas at 25 °C, 101.3 kPa)	192.731 J mol^{-1} K^{-1}
Free enthalpy of formation (gas at 25 °C, 101.3 kPa)	–16.391 kJ/mol
Net heating value, *LHV*	18.577 kJ/g
Gross heating value, *HHV*	22.543 kJ/g
Electrical conductivity (at –35 °C), very pure	1×10^{-11} Ω^{-1} cm^{-1}
Commercial	3×10^{-5} Ω^{-1} cm^{-1}
Ignition temperature acc. to DIN 51794	651 °C
Explosive limits	
NH_3 – O_2 mixture	
(at 20 °C, 101.3 kPa)	15 – 79 vol % NH_3
NH_3 –air mixture	
(at 0 °C, 101.3 kPa)	16 – 27 vol % NH_3
(at 100 °C, 101.3 kPa)	15.5 – 28 vol % NH_3

p – V – T Data. The *p – V – T* data in Table 2 are calculated from the equations in [12] and further data in [9], [13-18]. Measured *p – V – T* values for liquid ammonia in the pressure range from 7 to 180 MPa (70 – 1800 bar) and at temperatures from –20 °C to 40 °C may be found in [19]. Detailed information on compressibility gained from experimental data can be found in [24-29]. An equation of state for liquid ammonia is given in [20]; for a more simple form, see [16]. Further data may be found in references [21-23]. Properties of liquid ammonia from –50 to 65 °C and from saturation pressure up to 370 bar are reported in [30].

Caloric Data. Enthalpy and entropy of solid ammonia are given in [13]. Enthalpy and entropy may be calculated by the equations in [12]. Further data are given in [9-11] and [13-18]. An enthalpy log *p* diagram can be found in [18].

Specific Heat. In the range of – 45 °C to 50 °C the specific heat (in kJ kg^{-1} K^{-1}) of liquid ammonia can be calculated using the equation:

$$c_p = -3.787 + 0.0949\,T - 0.3734 \times 10^{-3}\,T^2 + 0.5064 \times 10^{-6}\,T^3$$

where $T = \vartheta + 273.15$.

Assuming ammonia to be an ideal gas in the range 300 – 2000 K the following equation represents the specific heat:

$$c_p = 1.4780 + 2.09307 \times 10^{-3}\,T - 2.0019 \times 10^{-7}\,T^2 - 8.07923 \times 10^{-11}\,T^3$$

The values of the specific heat at constant pressure in Table 3 have been calculated according to [12] and have been extrapolated to 500 °C using data from [9]. Further data can be found in [13-17], [31] and [32].

Vapor – Liquid Equilibria for the Ammonia, Hydrogen, Nitrogen, Argon, Methane System (Fig. 2). Because of the great importance of absorption processes in synthesis loop engineering (see Section Inert-Gas and Purge-Gas Management), these binary and multicomponent systems have come under experimental and theoretical reexamination. The new efforts are characterized above all by consideration of thermodynamic relationships in combination with equations of state.

Figure 2. Equilibrium solubilities (*K* factors) for argon (A), hydrogen (B), nitrogen (C), hydrogen : nitrogen 3 : 1 (D), and methane : nitrogen in liquid ammonia (E). F shows the dependence of the methane partial pressure ($p \cdot yCH_4$) on the concentration of methane dissolved in the liquid, xCH_4, for three different gas mixtures

A – C and E according to [48], F according to [44], D was developed from data reported in [46]

In [35] various publications are compared with one another and equilibrium methods for the ranges 273 – 323 K and 4.9 – 49 MPa (49 to 490 bar) are reported. Investigations of binary systems are reported in [36-44] and equations and compilations in [45], [46], and [399], among others. The basis for the saturation concentration (Table 5) and solubilities in liquid ammonia (Table 6) are unpublished BASF calculations produced with the help of the Lee – Kesler equation of state [47] and publications [37-46]. The ammonia content of the gas may be calculated with the formulas from [40].

A mutual interaction of solubilities exists in all multicomponent systems. The interaction with methane is pronounced. This interdependence is treated in detail in [44] and [49-51].

Surface Tension. The following equation, from [52], represents the surface tension of ammonia (σ in Nm^{-1}) over the range –50 to 50 °C.

$$\sigma = 26.55 \times 10^{-3} - 2.3 \times 10^{-4}\vartheta$$

Experimental data are given in [53]. The surface tension of aqueous ammonia solutions over the ranges 0.1 – 1.2 MPa (1 – 12 bar) and 20 – 100 °C can be found in [54].

Dynamic Viscosity. A survey on dynamic viscosity data for the ranges 30 – 250 °C and 0.1 – 80 MPa (1 – 800 bar) appears in [15]; further data occur in [55] and [56]. Experimental viscosity data and correlating equations for the range 448 – 598 K and for pressures up to 12.1 MPa (121 bar) can be found in [57]. Generalized equations for viscosity calculations on refrigerants are presented in [58].

The following, from [52], is a formula for interpolation along the vapor pressure curve for liquid ammonia (viscosity η in N s m^{-2}):

$$\eta = 1.949 \times 10^{-4} - 1.72 \times 10^{-6}\vartheta + 7 \times 10^{-10}\vartheta^2$$

An interpolation formula for ammonia vapor for the temperature range –20 to 150 °C at 0.098 MPa is given in [52]:

$$\eta = 9.83 \times 10^{-6} + 2.75 \times 10^{-8}\vartheta + 2.8 \times 10^{-11}\vartheta^2$$

Reference [59] reports viscosity measurements for the hydrogen – ammonia system; [60] for nitrogen – ammonia, oxygen – ammonia, methane – ammonia, and ethylene – ammonia; and [61] for argon – ammonia.

Thermal Conductivity. In [62], experimental data and calculation methods for ammonia liquid and vapor for the ranges 0.1 – 49 MPa (1 – 490 bar) and 20 – 177 °C are reported. The anomaly in the thermal conductivity at the critical point is discussed in full detail. A nomogram for these data appears in [63]. A third-degree equation for the range 358 – 925 K can be found in [64]. For the liquid phase the following formula may be used to interpolate in the range from –10 to 100 °C [52] (thermal conductivity λ in W m^{-1} K^{-1}):

$$\lambda = 0.528 - 1.669 \times 10^{-2}\vartheta - 6.2 \times 10^{-6}\vartheta^2$$

Also from [52] is the formula for ammonia vapor at 101.3 kPa and –20 to 150 °C:

$$\lambda = 0.0217 + 1.17 \times 10^{-4}\vartheta + 1.87 \times 10^{-2}\vartheta^2$$

The thermal conductivities of gas mixtures of ammonia with argon, neon, hydrogen, and methane are reported in [60] and [65-67].

Solubility in Water. Tables 7 and 8 and Figures 3 and 4 show miscellaneous information. General physicochemical and chemical engineering handbooks can be consulted for further data.

Table 7. Table for determining the percentage ammonia content of aqueous solutions from the density at 15 °C

Isotherms

Reference [68] gives *p* – *V* – *T* values for ammonia containing up to 0.5 wt % water at pressures in the range 113 – 221 kPa.

Solubility in Liquid Ammonia. Liquid ammonia is a good solvent for many salts as well as for some metals and nonmetals. Because of its dipole moment, the ammonia molecule interacts with these ions to form solvates in a manner analogous to the water molecule in aqueous solutions. Solutions in liquid ammonia show significant electrical conductance. Pure ammonia, like water, itself has a conductivity that, although limited, is based on dissociation according to:

$$2\,NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$

Inorganic salts such as nitrates, nitrites, iodides, cyanides, thiocyanides, and acetates are very soluble in liquid ammonia. The hydroxides, fluorides, and salts with di- and trivalent anions, such as oxides and sulfides, in general are insoluble. Ammonium salts are especially soluble.

A compilation of the solubilities of organic compounds in liquid ammonia shows notable solubility of saccharoses [76].

Liquid ammonia in combination with water as antisolvent and methylamine as prosolvent is also an excellent extraction medium for all types of petroleum fractions [81].

[Top of Page]

3. Chemical Properties

The ionic complex NH_4^+ results from addition of a proton to the ammonia molecule. This ammonium ion is similar to the alkali metal ions in its alkaline and salt-forming attributes.

The free radical NH_4 has been isolated only in the form of its amalgam (DAVY, 1811) which precipitates the more noble metals, such as copper, cadmium, and zinc, from their solutions. Solutions of ammonium in liquid ammonia are blue and usually exhibit properties similar to liquid ammonia solutions of sodium and potassium.

Aqueous solutions of ammonia react as weak bases because hydroxyl ions result from the addition of a proton or H_3O^+ from the water to the ammonia molecule. However, the equilibrium is very strongly shifted to the side of free ammonia, as may be seen from the equilibrium constant at 18 °C:

$$\frac{[NH_4^+][OH^-]}{[NH_3]} = K[H_2O] = K'_{NH_3} = 1.75 \times 10^{-5}$$

A 1 N solution of ammonium hydroxide has a pH of 11.77 – at 18 °C.

Ammonium salts result from reaction with acids in aqueous solution or in the gas phase (⟶ Ammonium Compounds).

Ammonia is oxidized by *oxygen* or air, depending on the reaction conditions, to NO, NO_2, or N_2O or to nitrogen and water. On alkaline surfaces, such as quicklime or soda lime, ammonia – air mixtures are oxidized readily at 350 °C to nitrite and further to nitrate. The reaction rate can be increased by adding traces of nickel and cobalt oxides to the catalyst surfaces [69]. Gaseous ammonia reacts very violently or even explosively with nitrogen oxides to form nitrogen, water, ammonium nitrate or nitrite. The reaction with N_2O requires ignition. The controlled catalytic oxidation of ammonia to produce nitric acid or pure NO for hydroxylamine production is described in ⟶ Nitric Acid, Nitrous Acid, and Nitrogen Oxides – Industrial Production; ⟶ Hydroxylamine – Catalytic Hydrogenation of Nitric Oxide.

At higher temperatures, especially in the presence of surface-active materials, ammonia forms *hydrogen cyanide* with carbon monoxide, methane, or charcoal. The catalytic oxidation of methane in the presence of ammonia is employed for the industrial production of hydrogen cyanide. With CO_2, SO_3, and P_2O_5, NH_3 forms amides of carbonic acid (⟶ Urea), sulfuric acid (⟶ Sulfuric Acid and Sulfur Trioxide), and phosphoric acid (⟶ Phosphoric Acid and Phosphates).

Metals may replace one or all of the hydrogen atoms of ammonia. The *amide*, for example, sodium amide, $NaNH_2$, is obtained with evolution of hydrogen by passing ammonia vapor over metallic sodium. Sodium amide reacts with N_2O to form highly explosive sodium *azide*. An ammonium azide, NH_4N_3, may be prepared also. The *imide*, for example, lithium imide, Li_2NH, results from replacing a further hydrogen atom by metals. Finally, there are the *nitrides*, such as lithium or magnesium nitride, Li_3N or Mg_3N_2. The nitrides of reactive metals, such as lithium, magnesium, calcium, aluminum, and titanium, are formed directly from the elements at elevated temperature. In many cases, it is better to obtain nitrides through the action of ammonia on the metals or metal compounds at higher temperature. A nitride also may result from thermal decomposition of an amide.

Sulfur, phosphorus, and halogens also can take the place of the hydrogen atoms in ammonia. At relatively low temperatures, halogens react with ammonia to form *nitrogen – halogen compounds* and *ammonium halides*. At higher temperatures the products are nitrogen and hydrogen halides. With sodium hypochlorite, ammonia forms *hydrazine hydrate* (Raschig synthesis) with chloramine, H_2NCl, as an intermediate.

Ammonia undergoes numerous industrially important reactions with organic compounds. Reaction with alkyl halides or alcohols serves to manufacture *amines* or *imines*. For example, methanol forms mono- through trimethylamine; dichloromethane yields ethylene imine in the presence of calcium oxide. With organic acid halides, the reaction leads to the *acid amide*, with elimination of hydrogen chloride. Likewise, acid amides result from acylating ammonia with esters, acid anhydrides, or the acids themselves (above 100 °C); for example, formamide from methyl formate. Catalytic hydrogenation converts the acid amides to *primary amines*. Adding ammonia to aldehydes and ketones and splitting off water leads through unstable, intermediate amino compounds to three different forms of stable end products: for example, on reaction with formaldehyde, *hexamethylenetetramine* (urotropine) is obtained; with acetaldehyde, *ammono acetaldehyde*, which can again be dissociated hydrolytically; and in the case of benzaldehyde, *hydrobenzamide*. With ethylene and propylene oxides, aqueous ammonia reacts to form *ethanol*- or *propanolamine*. By reaction of olefins with ammonia, especially employing corona electrical discharges, *alkylamines* can be obtained, e.g., up to 10 % yield of ethylamine, or 15 % of 1-aminopropane. Otherwise, these compounds may be prepared by decomposing the acid amide or by reacting ammonia with alkyl halides in multistage processes [70]. The catalytic gas-phase oxidation of olefins in the presence of ammonia on vanadium- or molybdenum-containing catalysts, so-called *ammonoxidation*, results in economic yields of the commercially important *acid nitriles*, for example, acrylonitrile from propylene [71]. Ammonoxidation of *o*-xylene yields phthalodinitrile in a single reaction step.

Reactions in Liquid Ammonia. Reactions in liquid ammonia [72] sometimes proceed differently from those in water because of the solubility difference of many salts between water and ammonia. For example, the reaction

$$2\,AgNO_3 + BaCl_2 \underset{NH_3}{\overset{H_2O}{\rightleftharpoons}} 2\,AgCl + Ba(NO_3)_2$$

leads in water to precipitation of silver chloride, and in ammonia, to precipitation of barium chloride. In liquid ammonia, ammonium salts have an “acid” character. For example, alkali and alkaline-earth metals, cerium, lanthanum, manganese, cobalt, nickel, and iron and its alloys are soluble in solutions of ammonium bromide, iodide, cyanide, and thiocyanide, with formation of the corresponding metal amine salt and evolution of hydrogen:

$$2\,NH_4^+ + Mg \rightarrow Mg^{2+} + 2\,NH_3 + H_2$$

Correspondingly, metal amides in liquid ammonia have a “basic” character. The reaction of ammonium salt with metal amide in liquid ammonia is analogous to the neutralization of acid and base in water. The heats of neutralization in ammonia are even larger than in water. The process of hydrolysis corresponds to ammonolysis in ammonia. This results in ammonobasic compounds, for example, in the infusible precipitate $HgNH_2Cl$ from $HgCl_2$.

Liquid ammonia is a good solvent for white phosphorus. Rhombic sulfur is dissolved by liquid ammonia at –11.5 °C. Once dissolved, at lower temperature a blue solution results in which partial ammonolysis of sulfur to sulfur nitride and ammonium sulfides or polysulfides takes place.

Liquid ammonia's ability to dissolve alkali and alkaline-earth metals has been well known for a long time. In concentrated solutions, the metals largely remain in the metallic state. The magnetic properties and the electrical conductivity, which is comparable to that of mercury, confirm this. In the more dilute blue solutions, the metals are completely dissociated to positive metal ions and solvated electrons [73]. The ammoniacal solutions allow preparation of many compounds otherwise unobtainable or obtainable only with difficulty. Examples are the sodium selenides, Na_2Se through Na_2Se_6, tellurides up to Na_2Te_4, antimonides, arsenides, polystannides, and polyplumbides. Introducing oxygen into the solution of alkali metals forms peroxides, Na_2O_2, K_2O_2, as well as dioxides, KO_2, RbO_2, and CsO_2. White explosive salts of the hypothetical acetylenediols, such as KO–C≡C–OK, result with carbon monoxide [74]; with acetylene, NaC≡CH; and with phosphine, KPH_2. Reactions of ammoniacal metal solutions with halogen-containing organic compounds can be used for the synthesis of higher hydrocarbons, amines, and free radicals. For example, reacting triphenylchloromethane with dissolved sodium produces the triphenylmethyl radical $Ph_3C^{\bullet}$.

A survey of organic reactions in liquid ammonia appears in [75].

[Top of Page]

4. Production

Ammonia is the second largest synthetic chemical product; more than 90 % of world consumption is manufactured from the elements nitrogen and hydrogen in a catalytic process originally developed by FRITZ HABER and CARL BOSCH using a promoted iron catalyst discovered by ALWIN MITTASCH. Since the early days there has been no fundamental change in this process. Even today the synthesis section of practically every ammonia plant has the same basic configuration as the first plants. A hydrogen – nitrogen mixture reacts over the iron catalyst (today's formulation differs little from the original) at elevated temperature in the range of 400 – 500 °C (originally up to 600 °C) and pressures above 100 bar with recycle of the unconverted part of the synthesis gas and separation of the ammonia product under high pressure. End of the 1990s a ruthenium-based catalyst was introduced which allows slightly lower synthesis pressure and is used in a few world-size plants (KAAP process of Kellogg – Braun – Root [1392-1394].

BOSCH was already well aware that the production of a pure hydrogen – nitrogen mixture is the largest single contributor to the total production cost of ammonia [93]. So, in contrast to the synthesis reaction, dramatic changes happened over the years in the technology of synthesis-gas generation, and technical ammonia processes differ today mainly with respect to synthesis-gas preparation and purification. The elements nitrogen and hydrogen are abundantly available in the form of air and water, from which they can be separated by physical methods and/or chemical reactions using almost exclusively fossil energy. The predominant fossil fuels are natural gas, liquefied petroleum gas (LPG), naphtha, and higher petroleum fractions; coal or coke is used only under special economic and geographical conditions (China, India, South Africa). Recovery of ammonia as byproduct of other production processes, e.g., coke ovens, is no longer of great importance.

Of course, some of the hydrogen comes also from the hydrocarbons themselves (methane has the highest content), and the carbon acts as a reducing agent for water and in some processes may also facilitate the separation of oxygen from nitrogen by formation of carbon dioxide which can be removed by various operations.

4.1. Historical Development

The catalytic synthesis of ammonia from its elements is one of the greatest achievements of industrial chemistry. This process not only solved a fundamental problem in securing our food supply by production of fertilizers but also opened a new phase of industrial chemistry by laying the foundations for subsequent high-pressure processes like methanol synthesis, oxo synthesis, Fischer – Tropsch Process, coal liquefaction, and Reppe reactions. Continuous ammonia production with high space yields on large scale combined with the ammonia oxidation process for nitric acid, which was developed immediately after ammonia synthesis, enabled the chemical industry for the first time to compete successfully against a cheap natural bulk product, namely, sodium nitrate imported from Chile.

The driving force in the search for methods of nitrogen fixation, of course, was to produce fertilizers. In principle there are three ways of breaking the bond of the nitrogen molecule and fixing the element in a compound:

1. To combine the atmospheric elements nitrogen and oxygen directly to form nitric oxides
2. To combine nitrogen and hydrogen to give ammonia
3. To use compounds capable of fixing nitrogen in their structure under certain reaction conditions.

A vast amount of research in all three directions led to commercial processes for each of them: the electric arc process, the cyanamid process, and ammonia synthesis, which finally displaced the other two and rendered them obsolete.

The availability of cheap hydrolelectric power in Norway and the United States stimulated the development of the *electric arc process*. Air was passed through an electric arc which raised its temperature to 3000 °C, where nitrogen and oxygen combine to give nitric oxide. In 1904 CHRISTIAN BIRKELAND performed successful experiments and, together with SAM EYDE, an industrial process was developed and a commercial plant was built, which by 1908 was already producing 7000 t of fixed nitrogen. Working in parallel, SCHOENHERR at BASF developed a different electric arc furnace in 1905. The Norwegians and BASF combined forces in 1912 to build a new commercial plant in Norway. However, since at this time pilot-plant operation of ammonia synthesis was already successful, BASF withdrew from this joint venture soon after. Nevertheless, the Norwegian plants operated throughout World War I and had total production of 28 000 t/a of fixed nitrogen with a power consumption of 210 000 kW [33]. The specific energy consumption was tremendous: 60 000 kW per tonne of fixed nitrogen. Had this electricity been generated from fossil fuels this figure would correspond to about 600 GJ per tonne nitrogen, which is about 17 times the consumption of an advanced steam-reforming ammonia plant in 1996.

The cyanamide process, [33], [77-79], developed by FRANK and CARO in 1898, was commercially established by 1910. Calcium carbide, formed from coke and lime in a carbide furnace (⟶ Calcium Carbide), reacts with nitrogen to give calcium cyanamide, which can be decomposed with water to yield ammonia. The process was energetically very inefficient, consuming 190 GJ per tonne of ammonia. Some other routes via barium cyanide produced from barytes, coke and nitrogen, or using the formation of titanium nitride were investigated in Ludwigshafen by BOSCH and MITTASCH but did not appear promising. In 1934, 11 % of world nitrogen production (about 2×10^6 t/a) [80] was still based on the cyanamide process, and some plants even continued to operate after World War II.

After BERTHOLLET proved in 1784 that ammonia consists of nitrogen and hydrogen and was also able to establish the approximate ratio between these elements, many experiments in the 1800s were aimed at its *direct synthesis*, but remained unsuccessful [82-84]. One of the reasons for the lack of success was the limited knowledge of thermodynamics and the incomplete understanding of the law of mass action and chemical equilibrium. It was the new science of physical chemistry, which developed rapidly in the late 1800s, that enabled chemists to investigate ammonia formation more systematically.

Around 1900 FRITZ HABER began to investigate the ammonia equilibrium [85] at atmospheric pressure and found minimal ammonia concentrations at around 1000 °C (0.012 %). Apart from HABER, OSTWALD and NERNST were also closely involved in the ammonia synthesis problem, but a series of mistakes and misunderstandings occurred during the research. For example, OSTWALD withdrew a patent application for an iron ammonia synthesis catalyst because of an erroneous experiment, while NERNST concluded that commercial ammonia synthesis was not feasible in view of the low conversion he found when he first measured the equilibrium at 50 – 70 bar [257], [86].

After a controversy with NERNST, HABER repeated his measurements at atmospheric pressure and subsequently at higher pressures [87-90], overcoming his colleague's preoccupation with the unfavorable equilibrium concentrations. HABER concluded that much higher pressures had to be employed and that, perhaps more importantly, a recycle process was necessary.

The amount of ammonia formed in a single pass of the synthesis gas over the catalyst is much too small to be of interest for an economic production. HABER therefore recycled the unconverted synthesis gas. After separating the ammonia by condensation under synthesis pressure and supplementing with fresh synthesis gas to make-up for the portion converted to ammonia, the gas was recirculated by means of a circulation compressor to the catalyst-containing reactor. This process, described in the patent DRP 235 421 (1908), became the basis for the industrial manufacture of ammonia and since then the same principle has found widespread application in numerous high-pressure processes. HABER also anticipated the preheating of the synthesis gas to reaction temperature (at that time 600 °C) by heat exchange with the hot exhaust gas from the reactor, the temperature of which would be raised by the exothermic ammonia formation reaction sufficiently (about 18 °C temperature rise for a 1 % increase of the ammonia concentration in converted synthesis gas).

In 1908 HABER approached BASF (Badische Anilin & Soda Fabrik at that time) to seek support for his work and to discuss the possibilities for the realization of an industrial process. His successful demonstration in April 1909 of a small laboratory scale ammonia plant having all the features described above finally convinced the BASF representatives, and the company's board decided to pursue the technical development of the process with all available resources. In an unprecedented effort, CARL BOSCH, together with a team of dedicated and highly skilled co-workers, succeeded in developing a commercial process in less than five years [91-98]. The first plant started production at Oppau in September 1913 and had a daily capacity of 30 t of ammonia. Expansions increased the capacity to about 250 t/d in 1916/17 and a second plant with a capacity of 36 000 t/a went on stream in 1917 in Leuna. Further stepwise expansions, finally reaching 240 000 t/a, already decided in 1916, came in full production only after World War I [77]. After World War I ammonia plants were built in England, France, Italy, and many other countries based on a BASF license or own process developments, with modified process parameters, but using the same catalyst.

Up to the end of World War II, plant capacities were expanded by installing parallel lines of 70 – 120-t/d units, and synthesis-gas generation continued to be based on coal until the 1950s. With growing availability of cheap petrochemical feedstocks and novel cost-saving gasification processes (steam reforming and partial oxidation) a new age dawned in the ammonia industry. The development started in the USA, where steam reforming of natural gas was used for synthesis gas production. This process was originally developed by BASF and greatly improved by ICI, who extended it to naphtha feedstocks. Before natural gas became available in large quantities in Europe, partial oxidation of heavy oil fractions was used in several plants. The next revolution in the ammonia industry was the advent of the single-train steam reforming ammonia plants, pioneered by M. W. KELLOGG and others. The design philosophy was to use a single-train for large capacities (no parallel lines) and to be as far as possible energetically self-sufficient (no energy import) by having a high degree of energy integration (process steps in surplus supplying those in deficit). Only through this innovative plant concept with its drastic reduction in feedstock consumption and investment costs, could the enormous increase in world capacity in the following years became possible. Increasing competition and rising feedstock prices in the 1970s and 1980s forced industry and engineering companies to improve the processes further.

The LCA process of ICI (ICI LCA Process.) and the KRES/KAAP process, which is the first process since 1913 to use a non-iron synthesis catalyst, are recent advances that make a radical breakaway from established technology.

A short survey of the history of ammonia process technology can be found in [95], [96], [99], [100], [406], [1259], [1318], [1409].

4.2. Thermodynamic Data

Ammonia synthesis proceeds according to the following reaction:

$$0.5\,N_2 + 1.5\,H_2 \rightleftharpoons NH_3 \quad \Delta H_{298} = -46.22\,kJ/mol$$

To fix a kilogram of nitrogen in ammonia requires reacting 2.4 m^3 (STP) of hydrogen and 0.8 m^3 (STP) of nitrogen. About 3.27 MJ of heat is evolved. Table 9 is a compilation of the most important thermodynamic data for the reaction at atmospheric pressure.

Chemical Equilibrium. The reaction equilibrium has been investigated experimentally and theoretically many times. Values for the equilibrium constant are available for pressures up to 350 MPa (3500 bar).

GILLESPIE and BEATTIE [101] (see also [14]) were by far the most successful experimentally in establishing a firm basis for an analytical expression of the equilibrium constant in the range of industrial interest. The values in Tables 10 and 11 were calculated using their equation. A detailed description, with literature data and many tables, appears in [14]. A description of the equilibrium using the REDLICH – KWONG equation of state is given in [400].

Heat of Reaction. HABER investigated the heat of reaction at atmospheric pressure [102]. Numerous authors have estimated the pressure dependence under various assumptions. Today, most people use the Gillespie – Beattie equation [103]. This equation was used in calculating the values in Table 12. For further data see, for example, [14]. Reference [104] contains test results for the range 120 – 200 MPa (1200 – 2000 bar) and 450 – 525 °C. Additional literature can be found in [105]

Physical Properties of the Reactants. Various authors have measured the *p* – *V* – *T* behavior of nitrogen, hydrogen, and 3 : 1 hydrogen – nitrogen mixtures. Reference [14] contains a survey. For the specific heat, thermal conductivity, and viscosity of the reactants, see [106], [107]. It is to be noted that heats of mixing must be considered for synthesis gas. This applies especially for high pressures and low temperatures. Reference [108] gives viscosities of hydrogen – nitrogen and hydrogen – ammonia mixtures.

4.3. Ammonia Synthesis Reaction

4.3.1. *General Aspects*

Usually, a system having an exothermic heat of reaction under operating conditions should react spontaneously. However, to form ammonia from hydrogen and nitrogen molecules, significant energy input is required for the nitrogen molecule to achieve the activated state. This is because of its high dissociation energy of 941 kJ/mol, which is considerably higher than that of hydrogen. According to estimates [109], initiation of ammonia synthesis homogeneously in the gas phase

requires an activation energy of 230 – 420 kJ/mol. For purely thermal energy supply with a favorable collision yield, this activation barrier requires temperatures well above 800 – 1200 K to achieve measurable reaction rates. However, at such high temperatures and industrially reasonable pressures, the theoretically achievable ammonia yield is extremely small because of the unfavorable position of the thermodynamic equilibrium. In fact, all older attempts to combine molecular nitrogen purely thermally with atomic or molecular hydrogen failed. On the other hand, both ammonia and hydrazine result from reacting atomic nitrogen with atomic hydrogen (see for example [109, p. 186]).

At pressures above 200 MPa (2000 bar), the synthesis of ammonia proceeds even in the absence of specific catalysts. At such extreme pressures the vessel walls appear to catalyze the formation of ammonia.

In the homogeneous phase under thermodynamically favorable temperature conditions, the formation of ammonia may be forced by employing other forms of energy, such as electrical energy or ionizing radiation. The principal difficulty with these so-called plasma processes, which also impedes their economic use, is that the energy supplied is useful only in part for ammonia formation. A greater part is transformed in primary collision and exothermic secondary processes into undesirable heat or unusable incidental radiation.

In the catalytic combination of nitrogen and hydrogen, the molecules lose their translational degrees of freedom by fixation on the catalyst surface. This drastically reduces the required energy of activation, for example, to 103 kJ/mol on iron [110]. The reaction may then proceed in the temperature range 250 – 400 °C. In 1972, it was discovered that electron donor – acceptor (EDA) complexes permit making ammonia with measurable reaction rate at room temperature.

This section concentrates mainly on the ammonia synthesis reaction over iron catalysts and refers only briefly to reactions with non-iron catalysts. Iron catalysts which are generally used until today in commercial production units are composed in unreduced form of iron oxides (mainly magnetite) and a few percent of Al, Ca, and K; other elements such as Mg and Si may also be present in small amounts. Activation is usually accomplished in situ by reduction with synthesis gas. Prereduced catalysts are also commercially available.

Numerous investigations have been performed to elucidate the mechanism of catalytic reaction of nitrogen and hydrogen to form ammonia. References [111-114] give reviews of the older and some of the newer literature. Since the 1980s a large variety of surface science techniques involving Auger electron spectroscopy, X-ray photoelectron spectroscopy, work-function measurements, temperature-programmed adsorption and desorption, scanning tunnelling microscopy, and others have been developed [117], [118]. Many of these methods are based on interaction of slow electrons, ions, or neutral particles and exhibit high sensitivity to surface structures. With these powerful tools the kinetics of nitrogen and hydrogen adsorption and desorption could be investigated, and it was also possible to identify adsorbed intermediates. The results of these experiments allow the mechanism of ammonia synthesis in the pressure range of industrial interest to be elucidated [115, 116, 119].

As with every catalytic gas-phase reaction, the course of ammonia synthesis by the Haber – Bosch process can be divided into the following steps:

1. Transport of the reactants by diffusion and convection out of the bulk gas stream, through a laminar boundary layer, to the outer surface of the catalyst particles, and further through the pore system to the inner surface (pore walls)
2. Adsorption of the reactants (and catalyst poisons) on the inner surface
3. Reaction of the adsorbed species, if need be with participation by hydrogen from the gas phase, to form activated intermediate compounds
4. Desorption of the ammonia formed into the gas phase
5. Transport of the ammonia through the pore system and the laminar boundary layer into the bulk gas stream

Only the portion of the sequence that occurs on the catalyst surface is significant for the intrinsic catalytic reaction. Of special importance is the adsorption of nitrogen. This assumption is decisive in representing the synthesis reaction kinetics. The transport processes occurring in the pores of the catalyst in accordance with the classical laws of diffusion are of importance in industrial synthesis (see also Sections Particle Size and Shape and Kinetics).

4.3.2. *Catalyst Surface and Reaction Mechanism*

Earlier studies [142, 144-150, 157], [272] had already suggested that on iron catalysts nitrogen adsorption and dissociation can be regarded as the rate-determining step for the intrinsic reaction. This has now been fully confirmed by microkinetic simulations based on the results of surface science studies [115, 129, 151]. In single-crystal experiments it was found that the activation energy for dissociative nitrogen adsorption is not constant; it increases as the surface becomes increasingly covered with adsorbed nitrogen species. Under reaction conditions it can attain values of 63 – 84 kJ/mol [119, 141, 144, 145] which are typical for ammonia synthesis. In the case of nitrogen the first step seems to be an adsorption in molecular state followed by chemisorption in the atomic state. From experimental results it was concluded that for hydrogen a direct transition from the gaseous H_2 molecule into the chemisorbed H_{ad} is most likely, and evidence for the stepwise hydrogenation of surface nitrogen atomic species was found. In IR spectroscopic investigations, NH and NH_2 species were identified [152], and secondary ion emissions detecting NH^+ also confirmed the presence of NH species on the surface [180]. It was further shown that at lower temperatures nitrogen becomes adsorbed only in the molecular state, but subsequently dissociates when the temperature is raised. Isotopic experiments with $^{30}N_2$ and $^{29}N_2$ showed that the surface species resulting from low-temperature adsorption was molecular, whereas that from high-temperature adsorption was atomic [182]. Ammonia synthesis is highly sensitive to the orientation of the different crystal planes of iron in the catalyst [174-178]. Measurements on defined single crystal surfaces of pure iron performed under ultrahigh vacuum [153-155] clearly showed that Fe(111) is the most active surface. This was also demonstrated by the rate of ammonia formation on five different crystallographic planes for unpromoted iron at 20 bar, as shown in Figure 5.

Figure 5. Ammonia formation rate on different iron surfaces [123], [151]

Activation energy, reactivity, adhesion coefficient (the probability that a nitrogen molecule striking the surface will be adsorbed dissociatively) and work function show a clear dependence on surface orientation [123], [173]:

Ammonia synthesis activity:
(111) > (211) > (100) > (210) > (110)
Activation energy of nitrogen adsorption:
(111) > (100) > (110)
Work function:
(210) > (111) > (211) > (100) > (110)
Surface roughness:
(210) > (111) > (211) > (100) > (110)

Ultrahigh vacuum (UHV) experiments with single crystals show that the activation energy of the nitrogen adsorption at zero coverage increases from about zero for Fe (111) to 21 kJ/mol for Fe(110) [115], [144], [170-172]. These values increase significantly for higher coverage [171], [172]. Adsorption and desorption under higher pressure on finely dispersed catalyst indicate that the reaction is highly activated under these conditions with high coverage, about 100 kJ/mol [142], [143].

According to [170], [171] adsorption on the planes Fe(111) and Fe(110) is associated with a regrouping of the surface atoms.

A possible explanation for the high activity of faces (111) and (211) is that these are the only surfaces which expose C_7 sites (iron with seven nearest neighbors) to the reactant gases. There are theoretical arguments [160] that highly coordinated surface atoms should show increased catalytic activity due to low-energy charge fluctuations in the *d*-bands of these highly coordinated atoms. This argument might probably be the key for the special role of C_7 sites. Other reasons discussed are based on charge transfer and interaction of iron *d*-bands with antibonding 2 π^* orbitals of nitrogen [156].

Promotion with potassium of single iron crystals enhances the sticking probability for nitrogen dissociation much more on the Fe(100) and (110) than on the Fe(111)

(factors 280, ca. 1000 and 8, respectively) to the effect that the differences in surface orientation disappear [1316]. A similar effect was not found for the ammonia synthesis at 20 bar and catalyst temperature of 400 °C: only a two-fold increase of the ammonia formation rate was measured for Fe(111) and Fe(100), and the face (110) was found to be inactive with and without potassium [123]. Other experiments [158] show that even the least active face Fe(110) becomes as active for the synthesis as Fe(111) after addition of alumina with subsequent annealing with oxygen and water vapor. A proposed mechanism for these findings — backed by X-ray photoelectron spectroscopy, temperature programmed desorption and electron microscopy — assumes that first alumina forms an iron aluminate $FeAl_2O_4$ on the surface. This new surface then may serve as a template on which iron grows with (111) and (211) orientation upon exposure to the synthesis-gas mixture in the reaction [159].

Based on these experimental results a reaction scheme for the ammonia synthesis may be formulated comprising the following sequence of individual steps [115]:

$$H_2 + * \rightleftharpoons 2\,H_{ad} \quad (1)$$

$$N_2 + * \rightleftharpoons N_{2,ad} \quad (2)$$

$$N_{2,ad} \rightleftharpoons 2\,N_{ad} \quad (3)$$

$$N_{ad} + H_{ad} \rightleftharpoons NH_{ad} \quad (4)$$

$$NH_{ad} + H_{ad} \rightleftharpoons NH_{2,ad} \quad (5)$$

$$NH_{2,ad} + H_{ad} \rightleftharpoons NH_{3,ad} \quad (6)$$

$$NH_{3,ad} \rightleftharpoons NH_3 + * \quad (7)$$

The progress of the reaction may be described in the form of an energy profile, as shown in Figure 6. Industrial ammonia synthesis in the homogeneous gas phase is not feasible because of the high dissociation energies for the initial steps. The reaction over a catalyst avoids this problem since the energy gain associated with the surface atom bonds overcompensates these dissociation energies and the first steps have actually become exothermic.

Figure 6. Schematic energy profile of the progress of ammonia synthesis on Fe (energies in kJ/mol) [115]

Dissociative nitrogen adsorption remains nevertheless the rate-determinating step, not so much on account of its activation barrier but rather because of the very unfavorable pre-exponential factor in its rate constant. The subsequent hydrogenation steps are energetically uphill, but the energy differences involved can easily be overcome at the temperatures (ca. 700 K) used in industrial ammonia synthesis. It is, however, quite apparent that the rate-controlling step would switch from dissociative nitrogen adsorption to hydrogenation of adsorbed atomic nitrogen species if the temperature were lowered sufficiently because of these differences in activation energy.

Some critics [161] of the above energy diagram question the low net activation barrier from the gas phase. The arguments are based on an analysis of activation energies from early measurements of the nitrogen adsorption kinetics on singly (Al_2O_3) promoted catalysts and on the results of experiments with supersonic molecular beams [162], [163].

An attempt to explain these differences is given in [164]. In more recent investigations of the adsorbed nitrogen species [166-169] a second molecularly adsorbed species was detected. This so-called α state was interpreted as a bridge-bonded species with electron donation from the surface to the antibonding π levels of N_2, whereas the γ state is regarded as a terminally bound species. Thus the following picture for the nitrogen adsorption emerges:

$$N_2 \rightarrow S^* - N_2(\gamma\,\text{state}) \rightarrow S^* - N_2 - S^*(\alpha\,\text{state}) \rightarrow 2\,S^* - N(\beta\,\text{state})$$

where S* denotes a surface atom.

For industrial catalysts made by careful reduction of magnetite fused with nonreducible oxide promoters the important role of the (111) face seems to be confirmed [122]. However, the question whether the active industrial catalyst exposes mostly (111) faces remains unresolved. If not, further improvements of the catalyst are at least theoretically possible [165]. This was indeed the case with the new AmoMax-10 catalyst [1321], [1322] of Südchemie. This catalyst in its oxidic form is based on wustite instead of magnetite and has a significantly better activity at lower temperature than magnetite. Wustite is a nonstoichiometric iron oxide($Fe_{1-x}O$) with a cubic crystal structure, x ranging from 0.03 to 0.15. With still (111) faces present in the reduced state the catalyst has a higher specific surface area and an improved pore structure.

A critical evaluation of the present knowledge of the mechanism of the synthesis reaction was made by SCHLÖGL [172].

Other reaction mechanisms have been debated for reaction temperatures below 330 °C [126], [177], [179-190]. These propose participation of diatomic nitrogen, or of adsorption complexes containing diatomic nitrogen, in the rate-determining step (see 111, 112 for further literature).

NIELSEN et al. investigated ammonia synthesis on a commercial Topsøe catalyst, KM IR, over a wide temperature range. They found evidence that a different reaction mechanism predominates below and above 330 °C [191]. Also, at low temperatures, chemisorbed hydrogen blocks the catalyst surface [192]. The latter finding is in agreement with the observations of ERTL's group [141].

Reaction Mechanism on Non-Iron Catalysts. Non-iron systems which exhibit some potential to catalyze ammonia synthesis can be divided into the following groups [195]:

- Platinum group metals such as Ru, Os Ir, Pt (no nitrides)
- Mn, Co, Ni, Tc, Rh and their alloys (no nitride formation under synthesis conditions)
- Mn, Mo, V (present as nitrides under the reaction conditions)

In the non-iron systems the rate-determining step is also dissociative adsorption of nitrogen and the catalyst effectivity seems to be primarily dictated by the activation energy of the dissociation reaction [195]. This is somewhat surprising in view of the marked differences in the heats of adsorption of nitrogen and the adsorption activation energy. This even holds for tungsten, which has no significant activation energy and a high adsorption enthalpy for nitrogen, so that hydrogenation of adsorbed atomic nitrogen could be expected to be the rate-determining step. The factor common with the iron catalyst is the structure sensitivity.

The only system which seems to be promising for industrial application is ruthenium promoted with rubidium on graphite as carrier (see Section Commercial Ruthenium Catalysts). Further information on structure, activity and reaction mechanism of non-iron catalysts is given in [112], [195-197], [202]. Specific references: vanadium [193], uranium [194], molybdenum [198-200], tungsten [201].

4.3.3. *Kinetics*

Knowledge of the reaction kinetics is important for designing industrial ammonia synthesis reactors, for determining the optimal operating conditions, and for computer control of ammonia plants. This means predicting the technical dependence on operating variables of the rate of formation of ammonia in an integral catalyst volume element of a converter.

High pressure promotes a high rate of ammonia formation; high ammonia concentration in the synthesis gas (recycle gas) restricts it (Fig. 7). High temperatures accelerate ammonia formation but imply a lower value of the equilibrium ammonia concentration and so a lower driving force. Therefore, the rate of formation at first

increases with rising temperature but then goes through a maximum as the system approaches thermodynamic equilibrium (Fig. 8). A similar situation exists for the dependence of the reaction rate on the ratio of the hydrogen and nitrogen partial pressures; with lower temperature, the maximum rate shifts to a lower hydrogen – nitrogen ratio (Fig. 9). Figure 9 presents data obtained using a commercial iron catalyst, Topsøe KMIR. The data show a sharp drop in reaction rate with declining temperature at $H_2/N_2 = 3:1$ ratio in contrast to a $H_2/N_2 = 1:1$ ratio. This may be attributed to a hindering effect of adsorbed hydrogen at low temperature [192].

Figure 7. Reaction rate for NH_3 synthesis. Dependence on the ammonia concentration at various pressures.

Figure 8. Reaction rate for NH_3 synthesis. Dependence on the temperature at various pressures.

Figure 9. Ammonia synthesis rate constant dependence on hydrogen – nitrogen ratio

Equations for describing ammonia synthesis under industrial operating conditions must represent the influence of the temperature, the pressure, the gas composition, and the equilibrium composition. Moreover, they must also take into consideration the dependence of the ammonia formation rate on the concentration of catalyst poisons and the influence of mass-transfer resistances, which are significant in industrial ammonia synthesis.

Since the beginning of commercial ammonia synthesis, a large number of different kinetic equations have been suggested, emanating in each case from a proposed reaction mechanism or from empirical evaluations. A critical review of the data and equations published up to 1959 appears in [203]. A discussion of kinetics proposed up to 1970, insofar as they have been based on measurements in the operating range of commercial interest, can be found in [126]. An evaluation of present knowledge is given in [115], [127-129].

Contradictory data on the kinetics of ammonia synthesis, especially in the earlier literature, in some circumstances may reflect a lack of attention to the influence of impurities in the gas. If oxygen compounds are present in the synthesis gas, reversible poisoning of the adsorbing areas, in accordance with an equilibrium depending on the temperature and the water vapor – hydrogen partial pressure ratio, must be taken into account when developing rate equations (see also Section Catalyst Reduction).

Experimental Measurements of Reaction Kinetics. The reaction expressions discussed in the following model the intrinsic reaction on the catalyst surface, free of mass-transfer restrictions. Experimental measurements, usually made with very fine particles, are described by theoretically deduced formulas, the validity of which is tested experimentally by their possibility for extrapolation to other reaction conditions. Commonly the isothermal integral reactor is used with catalyst crushed to a size of 0.5 – 1.5 mm to avoid pore diffusion restriction and heat-transfer resistance in the catalyst particles. To exclude maldistribution effects and back mixing, a high ratio of bed length to bed diameter is chosen. Sometimes the catalyst is also diluted with inert material. In some investigations, differential reactors were used. To exclude any poisoning by the synthesis gas, very pure reactants were prepared by decomposition of anhydrous ammonia [127].

Classical Expressions for Ammonia Synthesis Kinetics. The first expression useful for engineering purposes was the Temkin – Pyzhev Equation (1) proposed in 1940 [204], [205]. It is based on the assumption that dissociative adsorption is the rate-determining step, that hydrogen and ammonia have no significant influence on nitrogen adsorption, and that the kinetics of nitrogen adsorption and desorption can be described adequately by Elovich-type adsorption on an energetically inhomogeneous surface. For many years this kinetic expression was the basic design equation for ammonia converters. Values for the factors α between 0.5 [207-209] and 0.75 [14], [210], [211] were used. A problem with this equation was that the α values (reaction order) were dependent on temperature, and the rate constants on pressure [191], [210-214]. More serious (not so much for industrial purposes, where the converter feed has always a certain ammonia content) was the fact that for zero ammonia content, as in some laboratory measurements, the equation gives an infinitely high reaction rate. To avoid this, a simpler expression (Eq. 2) was often used [212], [213].

$$(1)\quad v = k_1 p_{N_2}\left(\frac{p_{H_2}^3}{p_{NH_3}^2}\right)^{\alpha} - k_{-1}\left(\frac{p_{NH_3}^2}{p_{H_2}^3}\right)^{1-\alpha}$$

$\alpha = 0.5-0.75$

$$(2)\quad v = k' p_{H_2}^{\alpha} p_{N_2}^{1-\alpha}$$

Near equilibrium (fugacities instead of partial pressures in Eq. 1)

Higher pressure, some ammonia in the synthesis gas

Far from equilibrium

$$(3)\quad v = \frac{k_{-1}^0\left(a_{N_2}K_a^2 - \frac{a_{NH_3}^2}{a_{H_2}^3}\right)}{\left(1 + K_3\frac{a_{NH_3}}{a_{H_2}^w}\right)^{2\alpha}}$$

$w = 1.5;\ \alpha = 0.75$

$$(4)\quad v = \frac{k p_{N_2}^{1-\alpha}\left(1 - \frac{1}{K}\frac{p_{NH_3}^2}{p_{N_2}p_{H_2}^3}\right)}{\left(\frac{1}{p_{H_2}} + \frac{1}{K}\frac{p_{NH_3}^2}{p_{N_2}p_{H_2}^3}\right)^{\alpha}\left(1 + \frac{1}{p_{H_2}}\right)^{1-\alpha}}$$

An important modification was made by TEMKIN [206] who incorporated hydrogen addition to the adsorbed nitrogen as a second rate-determining step (Eq. 4). ICI demonstrated that this equation gives a better fit with experimental data [218]. It was also shown later that the original Equation (1) is a simplified form of a more general model which can be derived from the concept of energetically homogeneous (Langmuir – Hinshelwood adsorption isotherm) as well as for heterogeneous surfaces (Elovich-type isotherm). The applicability of a particular equation resulting from this concept also depends on the state of reduction of the catalyst [214, 215] and the type of promoter [216]. Equation (3), used by NIELSEN et al. [219], is a combination of these model equations, developed by OZAKI et al. [220], that uses fugacities instead of partial pressures. A similar equation is found in [217]. Additionally, a number of modified equations were proposed and tested with existing experimental data and industrial plant results [221-224]. Near the thermodynamical equilibrium, Equation (3) transforms into Equation (1) [191], [126].

Surface science based ammonia kinetics [115], [116], [127], [128] are presently still viewed as an academic exercise rather than as a practical tool for engineering. The large amount of available data on nitrogen and hydrogen adsorption from ultrahigh-vacuum studies on clean iron surfaces, acquired with all the modern spectroscopic techniques, has prompted some research groups, such as BOWKER et al. [226], [227] and STOLTZE and NØRSKOW [228], [229], to attempt the generation of a kinetic expression for ammonia synthesis from a detailed microscopic model of the reaction mechanism consisting of a number of discrete steps at molecular and atomic level. Potential energy diagrams for the various intermediate steps and species, were set up and Arrhenius expressions for each single step with known or estimated values for all pre-factors and activation energies were formulated. The best results have been achieved so far by calculating the overall rate from the rate of dissociation of the adsorbed nitrogen and equilibrium constants for all other reaction steps. The adsorption – desorption equilibria were treated with approximation of

competitive Langmuir-type adsorption and by evaluation of the partition functions for the gaseous and adsorbed species. The data from single-crystal experiments for potassium-promoted Fe(111) surface were used for the rate of the dissociative nitrogen adsorption. Comparison of the calculated ammonia yields with those determined experimentally on a commercial Topsøe KM1 catalyst showed an agreement within a factor better than 2. Figure 10 demonstrates these encouraging results. These conclusions have been confirmed by calculations results of another independent group [129], [231].

Figure 10. Comparison of ammonia concentrations calculated from surface science kinetics with experimentally measured values [229], [230]

To compete with the empirical models (Temkin and improved expressions) for the best fit to experimental data cannot be the prime objective of the microkinetic approaches. Rather, they are means of checking whether our knowledge and understanding of the elementary steps correspond to the reality of catalysts under industrial synthesis conditions.

Transport Phenomena. For practical application, the above kinetic equations have to be modified to make allowance for mass and energy transfer since the reaction rates actually observed in a commercial converter are lower. One aspect is interparticle mass transfer and heat transfer through the stagnant film which surrounds the catalyst particles. The high velocity of the gas passing through the converter creates sufficient turbulence to keep the film thickness rather small in relation to the catalyst grain size. For this reason the largest concentration gradient (with respect to the concentration in the bulk gas stream) is within the catalyst particles. Since the thermal conductivity of the iron catalysts is much higher than that of the synthesis gas, the major temperature difference is in the external gas film, while the catalyst particles themselves operate under approximately isothermal conditions. As can be seen from Table 13 the differences in temperature and ammonia concentration between the bulk gas stream and the external catalyst surface are small. It also appears that the effects are oppositely directed and will partly compensate each other. So it can be concluded that their combined influence on the reaction rate is negligible compared to inaccuracies of the experimental data for the intrinsic catalyst activity [127].

Table 13. Mass and heat transfer effects at the external surface of catalyst particle

Position in catalyst bed, vol% from inlet	NH_3 concentration in bulk gas, mol%	NH_3 concentration at catalyst surface, mol%	Temperature in bulk gas, °C	Temperature at catalyst surface, °C
0	2.500	2.592	400.0	401.4
20	4.500	4.288	428.1	429.5
40	5.960	6.045	455.1	456.5
60	7.000	7.778	481.9	483.2
80	9.300	9.361	505.5	506.6
100	10.500	10.536	522.7	523.3

For the particle sizes used in industrial reactors (≤ 1.5 mm), intra particle transport of the reactants and ammonia to and from the active inner catalyst surface may be slower than the intrinsic reaction rate and therefore cannot be neglected. The overall reaction can in this way be considerably limited by ammonia diffusion through the pores within the catalysts [225]. The ratio of the actual reaction rate to the intrinsic reaction rate (absence of mass transport restriction) has been termed as pore effectiveness factor *E*. This is often used as a correction factor for the rate equation constants in the engineering design of ammonia converters.

For pore diffusion resistances in reactions having moderate heat evolution, the following phenomena characteristically hold true in industrial ammonia synthesis [232]: in the temperature range in which transport limitation is operative, the apparent energy of activation falls to about half its value at low temperatures; the apparent activation energy and reaction order, as well as the ammonia production per unit volume of catalyst, decrease with increasing catalyst particle size [225][233-235]. For example at the gas inlet to a TVA converter, the effective rate of formation of ammonia on 5.7-mm particles is only about a quarter of the rate measured on very much smaller grains (Fig. 11) [126].

Figure 11. Ammonia content in the bulk stream (1) and in the catalyst pores (at r = 0.5 R) (2) and pore effectiveness factor, E (3)

21.4 MPa; 12 % inerts; SV = 15000 h^{-1}; particle diameter, 2 R = 5.7 mm

Mathematical models for calculating these effectiveness factors involve simultaneous differential equations, which on account of the complex kinetics of ammonia synthesis cannot be solved analytically. Exact numerical integration procedures, as adopted by various research groups [126], [238-240], are rather troublesome and time consuming even for a fast computer. A simplification [241] can be used which can be integrated analytically when the ammonia kinetics are approximated by a pseudo-first-order reaction [234-236], according to the equation:

$$r = k_v\left(c_{NH_3,\text{equilibrium}} - c_{NH_3}\right)$$

For this case, the pore effectiveness factor *E* is a function of the so-called Thiele modulus *m* [237]:

$$E = \frac{3}{m}\left[\frac{1}{\text{tnh}\ m} - \frac{1}{m}\right]$$

The Thiele modulus *m* is defined by

$$m = \frac{d_{eff}}{2}\sqrt{\frac{k_v}{D_{eff}}}$$

where

d_{eff} = effective particle diameter

D_{eff} = effective diffusion coefficient of ammonia in the catalyst particle

k_v = reaction rate constant referred to a unit of particle volume

tnh = hyperbolic tangent

The practical application of kinetic equations to the mathematical calculation of ammonia synthesis converters is described in [218], [238], [242-248].

4.4. Catalysts

The ammonia synthesis catalyst may be viewed as the heart of an ammonia plant. For a given operating pressure and desired production, it determines the operating temperature range, recycle gas flow, and refrigeration requirement. As a result, it directly fixes vessel and exchanger design in the synthesis loop. It also indirectly influences the make-up gas purity requirement, and so the operating pressure, and capital cost, and energy consumption for synthesis gas production and purification. Although the proportionate cost of catalysts compared to the total cost of a modern ammonia synthesis plant is negligible, the economics of the total

process are determined considerably by the performance of the ammonia catalyst [249].

Industrial catalysts for ammonia synthesis must satisfy the following requirements:

1. High *catalyst activity* at the lowest possible reaction temperatures in order to take advantage of the favorable thermodynamic equilibrium situation at low temperatures. Average commercial catalysts yield about 25 vol % ammonia when operating at 40 MPa (400 bar) and 480 °C catalyst end temperature, which corresponds to a 535 °C equilibrium temperature. With catalysts that would function at a reaction temperature about 100 K lower, a yield of 45 vol % ammonia can be expected with the same approach to equilibrium, or the pressure may be reduced to 15 MPa (compare Tables 9 and 10).
2. The highest possible *insensitivity to oxygen- and chlorine-containing catalyst poisons*, which may be present in even the very effectively purified synthesis gas of a modern process (see Sections Catalyst Poisons, and Gas Purification). In assessing the newly developed catalyst systems recommended for operation at very low temperatures (see Section Other Catalysts), it must be kept in mind that the effect of poisons, for example, oxygen compounds, may become more severe as temperature declines (see Fig. 23).
3. *Long life*, which is determined essentially by resistance to thermal degradation and to irreversible poisoning (see Section Catalyst Reduction). In older high-pressure plants (60 – 100 MPa), catalyst life was a big issue; because the catalysts in these plants showed a markedly reduced life owing to the severe operating conditions, the necessary downtime for removing, replacing, and reducing the catalyst had a considerable effect on the ammonia manufacturing cost. In modern single-train ammonia plants, conventional iron catalysts achieve service lifetimes up to 14 years.
4. *Mechanical Strength*. Insufficient pressure and abrasion resistance may lead to an excessive increase in converter pressure drop, and so to a premature plant shutdown. For example, mechanical disintegration during operation along with oxygen sensitivity thwarted the industrial application of uranium carbide catalysts [250].
5. Because of the high and increasing world demand for ammonia, a *reliable primary raw material source*. For example, osmium, which was planned as the first industrial catalyst, is so scarce that, in 1910, as a precautionary measure for this option, BASF had secured almost the total world supply [250].

The ammonia synthesis catalyst problem has been more intensively studied than the catalysis of any other industrial reaction. At BASF A. MITTASCH et al. started a tremendous program, in which up to 1911 more than 2500 different formulations were testet in more than 6500 runs. The experiments were finally brought to an end in 1922 after a total of 22 000 tests. They tested almost all elements of the periodic table for their suitability as ammonia catalysts [82], [251]. From these experiments came a series of technical findings, for example, concerning the relationships between catalytic effectiveness and the strength of the nitrogen bond and reducibility, or relating to the mechanism of opposing activation or inactivation in doubly promoted systems.

In principle, metals or metal alloys are suitable as ammonia catalysts, above all those from the transition-metal group [252] (Table 14). Metals or metal compounds for which the chemisorption energy of nitrogen is neither too high nor too low show the greatest effectiveness (Figs. 12, 13), [253], [254], so the magnetite-based catalyst proved suitable for industrial use.

Table 14. Effectiveness of various elements as catalysts, promoters, or catalyst poisons

	Catalysts	Promoters	Poisons
I		Li, Na, K, Rb, Cs	
II		Be, Mg, Ca, Ba, Sr	Cd, Zn

4.4.1. *Classical Iron Catalysts*

From the early days of ammonia production to the present, the only catalysts that have been used have been iron catalysts promoted with nonreducible oxides. Recently, a ruthenium-based catalyst promoted with rubidium has found industrial application. The basic composition of iron catalysts is still very similar to that of the first catalyst developed by BASF.

The catalytic activity of iron was already known well before the advent of industrial ammonia synthesis. RAMSAY and YOUNG used metallic iron for decomposing ammonia. PERMAN [255], as well as HABER and OØRDT [256], conducted the first catalytic synthesis experiments with iron at atmospheric pressure. NERNST [257] used elevated pressures of 5 – 7 MPa. Pure iron showed noticeable initial activity which, however, could be maintained for longer operating periods only with extremely pure synthesis gas.

The ammonia synthesis catalyst problem could be considered solved when the catalytic effectiveness of iron in conversion and its onstream life were successfully and substantially improved by adding reduction-resistant metal oxides [251] (Table 15). The iron catalysts promoted with aluminum and potassium oxides proved to be most serviceable [258]. Later, calcium was added as the third activator. Development work in the United States from 1922 can be found in [259].

Table 15. Effect of various elements or their oxides on the activity of iron catalysts in ammonia synthesis

a) positive:
Al, Ba, Be, Ca, Ce, Cr, Er, K, La, Li, Mg, Mn, Mo, Na, Nb, Nd, Rb, Sm, Sr, Ta, Th, Ti, U, V, W, Y, Zr

b) negative:
As, B, Bi, Br, C, Cd, Cl, F, J, P, Pb, S, Sb, Sn, Te, Tl, Zn

c) doubtful:
Au, Co, Cu, Hg, Ir, Ni, Os, Pd, Pt, Si

Modern catalysts additionally contain other promoters that were present in the older catalysts only as natural impurities from the raw materials. Onstream life and performance were enhanced considerably by optimizing the component ratios (Section Composition), conditions of preparation (Section Catalyst-Precursor Manufacture), and catalyst particle size and form (Section Particle Size and Shape). The high-purity gas of modern processes and the trend to lower synthesis pressures especially favor the development of more active and easily reducible types of catalysts, at some sacrifice in temperature stability and resistance to poisons. To some extent even today, ammonia plant operating conditions and types of converters (Section Formation of Ammonia in the Converter) can differ greatly one from another. Thus, individual catalyst manufacturers now offer several catalyst types in various particle size distributions, in oxidic and prereduced states.

4.4.1.1. *Composition*

Table 16 gives a composition survey of commercial ammonia catalysts in the years 1964 – 1966. The principal component of oxidic catalysts is more or less stoichiometric magnetite, Fe_3O_4, which transforms after reduction into the catalytically active form of α-iron.

Table 16. Examples of commercial ammonia catalysts from the years 1964 – 1966. Values for the composition in weight %. The numbers at the beginning of the lines are keyed to the catalyst origin.

Origin, type	Fe total	FeO	Fe_2O_3	Al_2O_3	MgO	SiO_2	CaO	K_2O	Other	Particle size, mm	Bulk density, kg/L

The degree of oxidation of industrial catalysts has a considerable influence on their catalytic properties. MITTASCH in 1909 established that catalysts manufactured by reducing a magnetite phase were superior to those prepared from other oxides. For industrial catalysts, the highest ammonia yields are observed with an Fe(II) – Fe (III) ratio of 0.5 – 0.6, about the degree of oxidation of stoichiometrically composed magnetite [260-262] (Fig. 14). To obtain optimal catalyst composition, careful control of the manufacturing process, especially the melting conditions, which determine the oxygen content, is necessary.

Figure 14. Dependence of the ammonia yield on the degree of oxidation of the iron in the unreduced catalyst

In general, the catalysts contain varying quantities of the oxides of aluminum, potassium, calcium, magnesium, and silicon as promoters. Patents recommend adding sodium [263], beryllium [264], vanadium [265], uranium [307], or platinum [266]. Reference [267] describes cesium-containing catalysts. Catalysts patented by Lummus [268] and Ammonia Casale [269] contain cerium as additional promoter. ICI [270] has developed a cobalt-containing catalyst, as has Grande Paroisse [271].

Nature of the Surface of Commercial Iron Catalysts. Freshly reduced commercial iron catalysts that contain aluminum, potassium, and calcium oxides as basic promoters consist of approximately 30-nm primary crystallites; the spaces between them form an interconnecting system of pores. Besides a maximum at a pore radius of about 10 nm that originates on reduction of the Fe_3O_4 (magnetite) phase of the nonporous oxidic catalyst, the pore distribution curve (Fig. 15) generally shows a peak at 25 – 50 nm that is formed on reduction of the wustite phase [126], [130]. The pore volume measures 0.09 – 0.1 cm^3/g; with an apparent density of 4.8 – 4.9 g/cm^3, accordingly, the pores represent 44 – 46 % of the volume of a catalyst granule [14]. The surface of the walls of the pores, the so-called inner surface, amounts to about 15 m^2/g.

Figure 15. Pore size distribution of a commercial catalyst after reduction at various temperatures [130]

The novel AmoMax catalyst [1321], [1322] of Südchemie is iron-based but uses wustite instead of magnetite—which previously was considered undispensible for the production of industrial ammonia catalysts—has an improved pore structure and higher specific surface area.

The composition of the outermost atomic layers of the pore walls deviates considerably from the overall average concentrations. Auger electron spectroscopic (AES) measurements on an industrial catalyst (BASF S 6-10) have shown that a significant enrichment of the promoters into the surface results using the unreduced as well

as the reduced catalyst [119] (see Table 17). The free iron surface of the reduced BASF catalyst [119] and Topsøe catalyst KM-I [131] comprises only a fraction of the total surface, as could be deduced from the results of prior investigations [126], [132-138].

Table 17. Composition by volume of an industrial ammonia catalyst in comparison to the surface composition before and after reduction (an approximately 10^{-4} cm^2 size typical surface). Numerical values in atomic % [119]

	Fe	K	Al	Ca	O
Volume composition	40.5	0.35	2.0	1.7	53.2
Surface composition before reduction	8.6	36.1	10.7	4.7	40.0
Surface composition after reduction	11.0	27.0	17.0	4.0	41.0

The aluminum oxide promoter exists partly in the form of larger crystallites and, moreover, is relatively homogeneously distributed over the iron area of the surface, although with low concentration [119], [131]. After reduction, about 1 wt % of the alumina also remains statistically distributed in the form of $FeAl_2O_4$ molecular groups built into the α-iron lattice of the reduced catalyst [139], [140]. According to [119] the potassium, in the form of a K + O adsorbed layer, covers about 20 – 50 % of the iron surface. According to [130], [131], a correlation exists between the distribution of the potassium and that of aluminum and/or silicon. Calcium oxide segregates, essentially at the grain boundaries, into separate regions, probably as a mixture of the silicate and ferrite [121]. Auger spectroscopic investigations on reduced BASF and Topsøe catalysts reveal large local differences in composition [119], [130]. Large, apparently homogeneous regions that have originated from reduction of Fe_3O_4 crystallites alternate with nonhomogeneous regions that are formed by the reduction of FeO crystals or consist of amorphous phases [130].

Extensive studies in the last decade have provided a more refined picture of the morphology of the active catalyst (reduced state) and its precursor (oxidic state). A review is given in [124]. With methods such as scanning transmission electron microscopy (TEM) and electron microdiffraction a textural hierarchy has been modeled. Macroscopic particles in the reduced catalyst are confined by fracture lines running through a system of blocks consisting of stacks of slabs in parallel orientation. This structure is already preformed in the preparation of the catalyst precursor, and in the reduction process a further subdivision of the slabs into even smaller platelets might occur. This texture is stabilized by structural promoters, which act as spacers and “glue,” separating neighboring platelets and thus providing voids for the interconnection of the pore system. There is also evidence that the basal plane of many platelets has the Fe(111) orientation [122], [124].

Influence of the Promoters. Promoters can be arranged in different groups according to the specific action of the metal oxides:

Structural stabilizers, such as Al_2O_3, produce a high inner surface during reduction and stabilize it under thermal stress by restraining iron crystallite growth [158], [262], [273]. The ability of the various metal oxides to create a high specific surface decreases in the following order [274]:

$$Al_2O_3 > TiO_2 > Cr_2O_3 > MgO > MnO = CaO > SiO_2 > BeO$$

So-called *electronic promoters*, such as the alkali oxides, enhance the specific activity (based on a unit surface) of iron – alumina catalysts. However, they reduce the inner surface or lower the temperature stability and the resistance to oxygen-containing catalyst poisons [275], [276]. In the alkali-metal series, the promoter effect increases with increasing atomic radius, and the destructive effect with decreasing atomic radius [277]. In striving to improve the activity or stability of iron catalysts, a multitude of structural and electronic promoters has been investigated, among them rare-earth oxides [278], [279], such as Sm_2O_3 [280], Ho_2O_3, Dy_2O_3, and Er_2O_3 [281].

Promoter oxides that are reduced to the metal during the activation process and form an alloy with the iron (see also Section Other Catalysts) are a special group. Among those in use industrially, cobalt is of special interest [282], [283].

The effect of a given promoter depends on concentration and on the type of promoter combination and the operating conditions, especially the reaction temperature and the synthesis gas purity [265], [275], [277], [284-287].

A graphic picture is conveyed in [277] of how the activity of a quadruply promoted (4 % Al_2O_3 , 1 % K_2O, 1 % CaO, 1 % SiO_2) catalyst changes with varying promoter concentration and operating conditions (Fig. 16). Under normal operating conditions [14 – 45 MPa, 380 – 550 °C, 10 000 – 20 000 m^3 m^{-3} h^{-1} (STP)], the optimal activity corresponds to a composition of 2.5 – 3.5 % CaO, 2.3 – 5.0 % Al_2O_3, 0.8 – 1.2 % K_2O, and 0 – 1.2 % SiO_2 (Fig. 16 B). Raising or lowering the concentration of a particular oxide causes a reduction in activity. Changes in the potassium and aluminum oxide concentrations have an especially strong influence. Adding magnesium oxide decreases the catalyst performance. If before the test the catalyst is overheated at 700 °C for 72 h (Fig. 16 C) or poisoned with 2000 cm^3 water vapor per cubic meter of gas at 550 °C (Fig. 16 D), the optimum composition shifts to higher Al_2O_3 and SiO_2 and lower K_2O and CaO concentrations. Magnesium oxide addition now shows a favorable effect.

Figure 16. Dependence of the catalyst activity on various factors

A) Concentration of impurities; B) Concentration of promoters; C) Overheating to 700 °C with increasing promoter concentrations; D) Poisoning with water at increasing promoter concentrations

For ammonia plants operating at pressures up to 35 MPa (350 bar), catalyst end temperatures of 520 – 530 °C maximum, and with highly purified synthesis gas, the preferred catalysts contain 2.5 – 4.0 % Al_2O_3 , 0.5 – 1.2 % K_2O, 2.0 – 3.5 % CaO, 0 – 1.0 % MgO, and a natural content of about 0.2 – 0.5 % SiO_2 [262]. Less active but more poison- and temperature-resistant catalysts containing up to 3.6 % magnesium oxide were recommended for older plants, for example, classical Casale plants, which operated at up to 80 MPa (800 bar) pressure and in which catalyst end temperature reached 650 °C (see for example [14]). An industrial catalyst for operating temperatures up to 550 °C is stabilized against deterioration by 2 – 5 % V_2O_5 besides 3.5 – 4.0 % Al_2O_3, 2.0 – 2.5 % CaO, and 0.7 % K_2O [265]. For higher operating temperatures, still higher V_2O_5 contents are recommended. Silicon dioxide additions shift the optimum potassium oxide concentration to higher values [275]. For example, the Bulgarian catalyst K-31 contains 3.9 % Al_2O_3, 2.3 % CaO, 0.4 % MgO, 0.8 % SiO_2, and 1.8 % K_2O. An older Norsk Hydro catalyst, besides the usual additives, contained 1.14 % SiO_2 and 1.57 % K_2O. The ICI catalyst with composition 5.2 % CoO, 1.9 % CaO, 0.8 % K_2O, 2.5 % Al_2O_3 , 0.2 % MgO, 0.5 % SiO_2, remainder Fe_3O_4, is substantially more active than the conventional cobalt-free catalysts [270], [288]. Reducing the synthesis pressure and/or the synthesis temperature should enable application of the Lummus [268], [289] and Ammonia Casale [269] cerium-containing catalysts.

The effect of the promoters on the rate of reduction and the temperature required for reducing the iron oxide phase is also significant in industrial practice. The structural promoters, such as Al_2O_3, lower the rate of reduction [124], [290], [291]. Magnesium oxide-activated iron, said to be thermally stable up to 650 °C, needs a higher reduction temperature than aluminum oxide-promoted iron catalyst [292]. Greater differences in reducibility have also been observed in commercial catalysts with similar chemical composition [293] and in connection with particular oxide phases, such as $CaFe_3O_5$ and FeO [293-295]. Early work [296] referred to the rough parallels between the reducibility and the thermal stability of catalysts. All published experience appears to demonstrate that it is not possible to combine in a catalyst high thermal stability with easy reducibility and high activity at low temperatures. Hence it may be advantageous to use a combination of active and thermally-resistant catalysts in the same converter.

Mechanism of the Promoter Effect. The action of the so-called structural promoters (stabilizers), such as Al_2O_3, is closely associated with their solubilities in the iron oxide matrix of the unreduced catalyst or with the capability of the regular crystallizing magnetite to form solid solutions with iron – aluminum spinels [14], [297-299].

The solid solutions of Fe_3O_4 and the spinel $FeAl_2O_4$ have a miscibility gap below 850 °C [300]; at 500 °C, the solubility limit in the magnetite mixed crystal is a maximum of 7.5 % $FeAl_2O_4$, i.e., 3 % Al_2O_3, referred to iron. Higher alumina contents lead to separation into two phases, whereby only the portion dissolved in the magnetite phase appears to be responsible for the specific promoter action of alumina [132], [133], [301]. According to [302], there exists a close connection with the mechanism of the reduction which consists schematically of the following partial steps [303]:

1. Phase-boundary reaction of hydrogen with oxygen ions of the magnetite lattice, with formation of water vapor and release of electrons
2. Formation of metallic iron nuclei by combination the electrons with Fe^{2+} ions
3. Diffusion of Fe^{2+} ions and electrons to the nuclei and growth of the nuclei to iron crystals of various size

A more detailed discussion of the reduction mechanism is given in Section Catalyst Reduction.

In the presence of dissolved aluminum ions, at not too high a temperature, the diffusion rate of the iron ions in the magnetite lattice is low. Hence, nucleus formation proceeds rapidly relative to crystal growth. Therefore, small iron crystallites, about 30 nm, form with correspondingly large specific surfaces. The aluminum probably remains partly in the iron crystallite in the form of very small $FeAl_2O_4$ areas statistically distributed over the lattice [139], [140], [302], [305], where an $FeAl_2O_4$ molecule occupies seven α Fe lattice positions [112].

According to this concept, the stabilizer function of alumina reduces to paracrystalline lattice defects; an analogous effect is to be expected with Cr_2O_3, Sc_2O_3 , etc. [139], [305]. Another theory is based on the observation that during reduction part of the alumina precipitates with other promoters into the surface of the iron crystallite in a molecularly dispersed distribution [135], [306] or in small islands [131]. This “patchy” monolayer of alumina acts like a “spacer” between iron atoms of neighboring crystallites and prevents sintering by means of a “skin” effect [140]. (See also [112], [121], [130].)

Insofar as small crystals of nonreducible oxides dispersed on the internal interfaces of the basic structural units (platelets) will stabilize the active catalyst surface Fe (111), the paracrystallinity hypothesis will probably hold true. But the assumption that this will happen on a molecular level on each basic structural unit is not true. The unique texture and anisotropy of the ammonia catalyst is a thermodynamically metastable state. Impurity stabilization (structural promotion) kinetically prevents the transformation of platelet iron into isotropic crystals by Ostwald ripening [122]. Thus the primary function of alumina is to prevent sintering by acting as a spacer, and in part it may also contribute to stabilizing the Fe(111) faces [125], [165].

Calcium oxide, which also acts as a structural promoter [130] has a limited solubility in magnetite. It tends to stretch the magnetite lattice [112]. In the main, on cooling the magnetite melt, it separates at the grain boundaries as $CaFe_3O_5$ (at very rapid cooling rates) [293] and, in the presence of SiO_2, forms poorly reducible intermediate layers of calcium ferrite and silicates [130], [294]. In the reduced catalysts, it segregates between the iron crystallites [120], [137] and so possibly prevents sintering together at high operating temperatures. One may also presume that by partial neutralization of the “acid” components by calcium, more potassium is made available for activating the iron [218].

Potassium is likewise scarcely soluble in magnetite because of its ionic size [112]. In the unreduced catalysts, separate potassium- and iron-rich regions were found [119]. The appearance of a $K_2Fe_{22}O_{34}$ phase besides an unidentified phase, however, has been proved [308]. According to [309], during reduction, the emerging K_2O migrates to the iron crystallite surface. While doing this it reacts with the more or less homogeneously distributed aluminum (silicon) compounds. In this way, it is distributed over the iron phase. In the reduced catalysts, the potassium exists as a K + O adsorption layer that covers about 20 – 50 % of the iron surface [119]. According to [136], [310], potassium associates partly with the alumina in the surface, partly as KOH with iron [1282]. It was found that the enhancement of the catalysts' specific activity by potassium oxide is accompanied by a decrease in the electron work function [310-312]. The promoting effect of potassium seems to be based on two factors which probably act simultaneously. One mechanism is the lowering of the activation energy for the dissociative adsorption of nitrogen [111], [119]. The explanation is based on an electrostatic model [115], [156], [313]. As indicated by the strong decrease in the work function upon potassium adsorption, there is a considerable electronic charge transfer to the substrate, which creates a $M^{\delta-} – K^{\delta+}$ dipole. A nitrogen molecule adsorbed near such a site will experience a more pronounced back-bonding effect from the metal to its antibonding π orbitals. This will increase the bond strength to the metal and further weaken the N – N bond, as can be seen from a further reduction of the N – N stretching frequency [314]. The other effect consists of lowering the adsorption energy of ammonia, which avoids hindering of nitrogen adsorption by blocking (poisoning) of the catalyst surface by adsorbed ammonia molecules [109, p. 234], [119]; hence, potassium oxide ought to improve the catalyst performance less at low than at higher operating pressures [210 p. 316], [315].

The negative effect of K_2O concentrations higher than about 0.58 % has not been explained unequivocally [158]. With increasing potassium concentration, this manifests itself by the increasing size of the average iron crystallite or the decreasing specific surface in the reduced catalyst [275], [308]. Since potassium oxide prevents the formation of solid solutions between alumina and magnetite to a certain extent [316], the recrystallization-promoting effect of higher K_2O concentrations may be attributed to a lowering of the portion of alumina dissolved in the magnetite phase [308]. Remarks in [309] and [317] reveal another possible interpretation: the K_2O located at the phase boundary surface and not bound to acid or amphoteric oxides may be converted by water vapor concentrations over 10^{-2} ppm in the synthesis gas into potassium hydroxide or by hydrogen into potassium and potassium hydroxide, which would exist in molten form at operating conditions [309], [1282].

An extensive review on promoters can be found in [116].

4.4.1.2. *Particle Size and Shape*

The choice of particle size and shape of commercial ammonia catalysts is determined mainly by two factors:

1. Catalyst performance
2. Pressure drop

From the standpoint of space – time yield, it is desirable to use the finest possible particle, which, practically speaking, is about 1 – 2 mm (Fig. 17); however, with decreasing particle size, the pressure drop and the risk of destructive fluidization of the catalyst increase (Fig. 18).

Figure 17. Influence of the particle size on the ammonia production (BASF catalyst).

25 MPa; SV = 12 000 $m^3 m^{-3} h^{-1}$ (STP); gas composition (vol %): N_2 20.59, H_2 60.06, NH_3 2.55, Ar 5, CH_4 10

Figure 18. Pressure drop in the catalyst bed for various catalyst particle size ranges, from [14].

Depth of the catalyst bed, 7 m; reaction pressure 27.1 MPa; reaction temperature 450 °C

For processes operating at pressures of 25 – 45 MPa (250 – 450 bar) and at space velocities of 8000 – 20 000 $m^3 m^{-3} h^{-1}$ (STP) a grain size of 6 – 10 mm is

preferred. Larger granulations, for example, 8 – 15 mm or 14 – 20 mm, are used only in plants where the lowest possible pressure drop is essential because of very high gas velocities. In catalyst zones in which the ammonia formation rate is so high that the allowable temperature limits are exceeded, it may be advantageous to use coarse particles for suppressing the reaction. Radial-flow converters and the horizontal crossflow Kellog converter (Fig. 52), which operate at comparatively low gas velocities [318], allow the use of small granulations (1.5 – 3 or 2 – 4 mm) with optimal use of the converter volume. Fluidized-bed processes, which were explored especially in the Soviet Union, have so far been unsuccessful [319], [320].

Two effects cause the low production capacity of coarse-grained catalyst: first, large grain size retards transport of the ammonia from the particle interior into the bulk gas stream, because this proceeds only by slow diffusion through the pore system. Slow ammonia diffusion inhibits the rate of reaction. At the high reaction rate typical for the converter inlet layer, only a surface layer of the catalyst grains, about 1 – 2 mm thick, participates in the reaction.

The second effect is a consequence of the fact that a single catalyst grain in the oxidic state is reduced from the outside to the interior of the particle [321]: the water vapor produced in the grain interior by reduction comes into contact with already reduced catalyst on its way to the particle outer surface; this induces a severe recrystallization [14]. The effect is very significant. As an example, if the particle size increases from about 1 to 8 mm, the inner surface decreases from 11 – 16 m^2/g to 3 – 8 m^2/g [326].

To allow for the influence of various particle shapes and size distributions within a defined sieve fraction, in lay-out calculations it is customary to employ an effective particle diameter, d_{eff}, as nominal size. The diameter d_{eff} is defined as the ratio of equivalent diameter Λ and a form factor Ψ. Λ is equal to the diameter of a sphere with a volume equal to the (average) volume of the particles, and Ψ is the average ratio of the particle surface to the surface of a sphere of equal volume.

Table 18 shows the relation between the catalyst size classification, the equivalent particle diameter, and the percentage saving in catalyst or converter volume relative to the 6 – 10 mm standard size [288].

Table 18. Effect of catalyst size on catalyst volume

Catalyst size classification, mm	Approximate equivalent particle diameter, mm	Relative catalyst volume, %
6 – 10	7.5	100
4.5 – 8	5.5 – 6.5	92 – 95
3 – 6	4.5 – 4.7	88 – 90
1.5 – 3	2.0 – 2.2	80 – 82
1 – 1.5	1.2 – 1.3	77 – 79

An irregular grain shape, for example with a shape factor of 1.5, has a more favorable effective activity for the individual particle and for radial intermixing of mass and heat in an industrial converter [327] than a more cubic or spherical shape, with a shape factor close to one. According to a patent by Chemie Linz AG [328], the catalyst particle ought to be 2 – 20 times as long as it is broad, preferably 5 – 10 mm long and 1 – 2 mm thick (broad). On the other hand, regular shapes have the advantages of greater abrasion resistance and lower pressure drop (see Fig. 19) [401].

Figure 19. Comparison of the Ammonia Casale spherical catalyst and irregularly shaped catalyst [288]

The advantages of regular catalyst shapes and the need to compensate for the above-described negative effects of larger grain size by a system of macropores in the oxidic and reduced catalyst stimulated various attempts to manufacture shaped, macroporous catalysts. Various manufacturing techniques have been proposed [329-338]. As an example, magnetite is melted with the additives at high temperature (> 1600 °C) and the melt is cooled, broken, and ground to powder. After water is added and, if required, a binding agent, such as bentonite [337], or a promoter salt, such as cerium nitrate [269], the powder is pelletized. The pellets subsequently are dried and sintered in an inert atmosphere at higher temperatures (about 1350 °C).

The application of macroporous catalysts ought to be especially useful for very low synthesis pressures and in plants in which large catalyst particles must be used for reasons of low pressure drop. For example, the performance of the macroporous Topsøe catalyst KMG 6 mm at 5 MPa synthesis pressure is said to be at least equivalent to KM I 1.5 – 3 mm and distinctly superior to KM I 6 – 10 mm [339].

4.4.1.3. *Catalyst-Precursor Manufacture*

The term “ammonia catalyst” commonly refers to the oxidic form consisting of magnetite and oxidic promoters. In fact this is only the catalyst precursor which is transformed into the active catalyst composed of α-iron and promoters by reduction with synthesis gas, usually in situ. The reduction step is very important for catalyst performance.

The first effective catalysts were made by the oxygen-melt process. The purest possible iron (e.g., Swedish charcoal iron), together with the additives, was burned to Fe_3O_4 in a stream of oxygen. This process was largely replaced by melt processes in which natural or, less frequently, synthetic magnetite, together with the activators, was melted electrically or in electric arc furnaces [261], [340]. The cooled melt is ground to the proper granulation and reduced with hydrogen – nitrogen mixtures.

A process developed by Farbenfabriken (formerly Friedrich Bayer) had only local significance. Complex iron cyanides were decomposed thermally in the presence of hydrogen. The hydrodecomposition proceeds via the carbide and nitride, finally to α iron. This is activated in the well-known manner by reduction-resistant metal oxides. The so-called Mont Cenis process employed such catalysts [341]. Repeatedly described as a means of manufacture, although only in the scientific literature, is coprecipitation of the catalyst components, for example, from aqueous solutions of the metal salts, with subsequent calcining and reduction [342-345]. With magnesium oxide as support, very small (under 10 nm) iron particles are obtained with high specific iron surfaces [345], similar to those obtained by exchange of magnesium ions by iron ions in the surfaces of magnesium hydroxy carbonate crystals [345], [346]. Granulation and sintering techniques have been used for the preparation of shaped macroporous iron catalysts, which, however, have not gained industrial importance.

Impregnating the pore surface of prereduced passivated catalysts is a possibility for incorporating promoters into iron ammonia catalysts. A United Kingdom patent [347], by way of example, claims catalysts manufactured by impregnating the reduced catalysts with cerium salts. Improving the performance and life of industrial catalysts by radioactivity and X-rays [348], treatment with ultrasound [349], [350], mechanical treatment [351], or high-frequency, alternating-field heating [352] has been attempted also.

The superiority of the catalyst manufacturing processes that use a molten iron oxide stage is mainly due to the fact that above 1000 °C in air, magnetite, Fe_3O_4, is the thermodynamically stable oxide phase of iron [82], [353]. Magnetite leads to especially efficient catalysts, and its electrical conductivity allows the use of economical electrical melting processes.

In 1996 the prices of commercial ammonia catalysts were about 2 $/lb (3.58 €/kg) for oxidic and about 5.5 $/lb (10.23 €/kg) for prereduced. Therefore, they are among the least expensive catalysts.

Operating conditions in the individual manufacturing steps — proportioning and mixing the raw materials, melting, cooling, crushing or if necessary grinding and preforming, and reduction — influence the quality of the finished catalyst (Fig. 20) [249].

Figure 20. Ammonia catalyst manufacture

The raw materials — usually, natural magnetite, lime, potash, and alumina — must, as far as possible, be free of catalyst poisons (see Section Catalyst Poisons). Many ores have too high a content of free or bound silica, which can be lowered with magnetic separators [354]. Melting is accomplished in electrical resistance or induction furnaces (arc furnaces in the past) operating at 1600 – 2000 °C. The walls of these furnaces should consist of a weakly basic tamping material indifferent to the melt, such as magnesium oxide, which is also an activating component of the catalyst [355]. A homogeneous distribution of the promoters in the magnetite melt and a degree of oxidation at or under that of stoichiometric magnetite should be obtained. This is said to be promoted by initially overheating to temperatures up to 3500 °C [356] (Fig. 21). It is claimed to be advantageous to bring the promoters into the melt as common chemical compounds that are isomorphous with magnetite [357].

Figure 21. Effect of the melting temperature and rate of cooling of the melt on the activity of ammonia catalysts

a) Melt overheated to 3500 °C (rapid cooling); b) Melt temperature 1800 – 2000 °C (rapid cooling); c) Melt temperature 1800 – 2000 °C (slow cooling)

Induction furnaces are optimal for the melting operation. Their good temperature control permits accurate adjustment of the degree of oxidation. Since the melt is held in constant turbulent motion by the magnetic field produced in the primary coil, it is well mixed, even for short melt times. In comparison to the most frequently used resistance furnaces, plant cost and power consumption are higher.

Another important factor in catalyst manufacture is the melt cooling rate, which is affected by the design and dimensions of the ingot molds. Quenching or fast cooling in thin sheets leads to a less abrasion-resistant, sharp-edged chip after crushing. Very slow cooling results in a more cubic chip, but with inferior catalyst quality (Fig. 21). In practice, slow cooling is avoided.

With falling temperature, both the solubility of the activator oxides (see Mechanism of the Promoter Effect.) in magnetite and the rate of adjustment to the new phase equilibrium decline. Therefore, by rapid cooling of the melt the activator oxide distribution can be frozen in a condition corresponding to that of a higher temperature [358]. According to [293], there may exist relationships between the melt cooling rate, the appearance of certain phases, and the reducibility of the catalysts.

4.4.1.4. *Catalyst Reduction*

The reduction of oxidic catalyst is generally effected with synthesis gas. The magnetite is converted into a highly porous, high surface area, highly catalytically active form of α-iron. The promoters, with the exception of cobalt, are not reduced [14].

To ensure maximum effectiveness of the catalyst, a defined reduction procedure must be followed. Above all, it is important to hold the partial pressure of the resulting water vapor as low as possible and to insure that the water vapor does not come into contact with regions that have already been reduced. High temperature and high water vapor partial pressure markedly accelerate premature catalyst aging by recrystallization. Therefore, the reduction should be carried out at high gas velocities [about 5000 – 15 000 $m^3\ m^{-3}\ h^{-1}$ (STP)], at the lowest temperatures sufficient for complete reduction, and at not too high pressures (7 – 12 MPa in low-pressure, 25 – 30 MPa in high-pressure plants) to hold the exothermic formation of ammonia under better control during the reduction. When the reduction of the oxidic catalyst is carried out in the production plants, long reduction times are needed at low temperatures and low pressures with a consequential loss of production.

In practice, the reduction temperature is raised stepwise by using the exothermic heat of ammonia formation. The progress of the reduction is controlled according to the catalyst temperature and the water concentration by means of the synthesis gas flow. As a rough guideline, the water content of the gas effluent from the catalyst should not exceed 2 – 3 g/m^3 (STP). Under these conditions, depending on its size and operating pressure, a synthesis converter with a fresh load of oxidic catalyst attains its full production capacity in 4 – 10 d.

The minimum temperatures necessary for reduction are somewhat different for the various catalyst types. Catalysts conventionally employed in medium-pressure plants may be reduced from about 340 to 390 °C, although a slow induction period starts somewhat lower. Generally, temperatures above 440 °C are required to complete the reduction.

The reducibility of industrial catalysts is dependent on both the combination of promoters and the degree of oxidation. The FeO (wustite) phase is reduced faster and at lower temperatures than the Fe_3O_4 (magnetite) phase [293]. According to [293], the rather considerable differences in the reduction rates of commercial catalysts with similar compositions may be attributed to differences in manufacturing methods or operating conditions. Commonly, the manufacturers hold these in strict secrecy.

Some older publications deal with the influence of catalyst granulation on the optimum reducing conditions [360]. Directions for reduction in multibed converters that combine fine- and coarse-grained catalyst appear in [361]. The influence of the hydrogen/nitrogen ratio during reduction on the catalyst performance after reduction is discussed in [362].

The influence of the reduction conditions (gas flow rate, temperature in the range 300 – 600 °C, nitrogen content in the hydrogen in the range 0 – 100 %) on the production capacity of an ammonia catalyst has been investigated [368].

The gas/solid reaction between magnetite and hydrogen has been studied in great detail by rate measurements, microscopy, and X-ray diffraction [363-366]; a summary is given in [124]. On the atomic scale the reaction is controlled by two processes:

1. Metallic iron is formed from wustite by direct chemical reaction controlled in the initial phase by the reaction rate (activation energy ca. 65 kJ/mol) and in the final stage by diffusion processes involving hydrogen and water on the reaction site:

   $$FeO + H_2 \rightarrow Fe + H_2O$$

2. The chemical reaction creates an iron(II) ion concentration gradient in the solid. This gradient leads to a rapid diffusion of iron(II) ions from magnetite through wustite to the chemical reaction interface, where they are reduced and precipitated as iron nuclei. This is made possible by the structural defects of the wustite. The precipitation of further wustite nuclei on the magnetite/wustite reaction interface seems to be effected by ion/electron diffusion processes rather than by direct contact of magnetite with hydrogen [367]:

   $$O^{2-} + H_2 \rightarrow H_2O + 2\,e^-$$

   $$Fe_3O_4 + Fe^{2+} + 2\,e^- \rightarrow 4\,FeO$$

The topotactic reduction process leads to a core and shell structure which is visible under the optical microscope and is shown schematically in Figure 22 (a). Figure 22 (b) shows the wustite/magnetite interface as observed by electron microscopy [124]. This concept was developed for single-crystal magnetite grains, but the shell and core model is also valid for commercial polycrystalline catalysts [369], [124]. Information on the reduction kinetics, including industrial catalysts, can be found in [122], [321], [322-325]. Newer findings seem to question the shell and core model with the topotactic reaction interface [172]. On account of the simplifications involved this model should be regarded as a formalistic approach to describe the reaction kinetics rather than a mechanistic approximation. A more detailed atomistic picture leads to the assumption that there is no homogeneous topotactic reaction interface. According to this concept the active catalyst should not grow as a shell around a precursor core but as a core within an oxidic matrix.

Figure 22. Mechanism of catalyst reduction [117]

a) Reducibility of catalyst under standard conditions as a function of its porosity; b) Core and shell structure of catalyst; c) Reaction interface

Prereduced, stabilized catalyst types, introduced on the market some years ago, have gained a considerable market share. Prereduced catalysts have the full pore structure of active catalysts, although the pore surface has been oxidized to a depth of a few atomic layers to make these catalysts nonpyrophoric.

Reactivating such catalysts usually takes only 30 – 40 h. Ammonia formation begins at substantially lower temperatures, so that altogether the downtime of a production unit is reduced markedly. This and further advantages, such as reducing the risk of damaging the catalyst during activation by too high a local concentration of water, the quantitatively lower yield of aqueous ammonia solution (which can be added to the production), as well as the roughly 20 % lower bulk weight (which reduces the design loadings and costs of the internals of large converter units), make using prereduced catalysts increasingly attractive, especially in single-train plants, in spite of higher prices. The somewhat inferior mechanical strength is a disadvantage that requires special care when a charge is being loaded into the converter. When removed from the hydrogen – nitrogen atmosphere at low to moderate pressure in the producing furnace, the prereduced catalysts are pyrophoric and must be stabilized before transport and installation by passivating the surface. Usually, the method recommended by BURNETT is used. The reduced charge is treated with nitrogen containing 100 – 1000 ppm oxygen at 50 – 70 °C (maximum 95 °C) and a pressure of 0.1 – 0.2 MPa (1 – 2 bar) and up [359]. The reducible oxygen content of the prereduced catalyst ranges between 2 and 7 %. Part of this is only loosely bound and is removed in reactivation even below 200 – 300 °C.

Detailed data on the manufacturing steps most important to the catalyst performance, reduction, prereduction, passivating, and reactivation, appear in [14], including a discussion of the most important literature in this field.

4.4.1.5. *Catalyst Poisons*

The activity of an ammonia synthesis catalyst may be lowered by certain substances, commonly referred to as poisons. These substances can be minor gaseous constituents of the synthesis gas or solids introduced into the catalysts during the manufacturing procedure, derived from impurities in the natural magnetite from which the catalyst is made. These latter should not play a major role with catalysts from manufacturers of repute and are not discussed in detail in this section because of the proprietary nature of the production processes. General measures to avoid this sort of contamination include selecting a rather pure magnetite, the application of pretreatment processes, and the use of high-purity promoters. The melting process itself may also contribute to minimizing the content of some minor impurities. For gaseous poisons in the synthesis gas, a distinction can be made between permanent poisons that cause irreversible damage to the catalyst and temporary poisons which lower the activity while present in the synthesis gas. In contrast to temporary poisons, permanent poisons can be detected by chemical analysis. Oxygen-containing compounds such as H_2O, CO, CO_2, and O_2 are the most common temporary poisons encountered in ammonia synthesis.

Oxygen compounds have a reversible effect on iron catalysts at not too high temperatures. That is, the activity of a damaged catalyst may be practically completely restored by reduction with clean synthesis gas. Equivalent concentrations of oxygen compounds, for example, 100 ppm of O_2 or CO_2 and 200 ppm CO or H_2O, lead to the same degree of poisoning, presumably because as soon as they enter the catalyst bed they rapidly and completely transform into H_2O [14]. The damage depends approximately linearly on the quantity of adsorbed water taken up by the catalyst [370], which is proportional to $\sqrt{pH_2O}/\sqrt{pH_2}$ [371]. Corresponding to the adsorption equilibrium, the degree of poisoning therefore rises with growing partial pressure ratio, pH_2O/pH_2 and falls with increasing temperature.

Under the assumption of a displacement equilibrium in accordance with

$$(N_2)_{ads} + H_2O_{gas} + 2\,H_{2\,gas} \rightleftharpoons (O)_{ads} + 2\,NH_3$$

I. A. SMIRNOV et al. set up a rate equation for ammonia synthesis [372], [373] that takes the effect of water vapor into consideration over a wide range of temperature and pressure:

$$v = \frac{k_1 p_{N_2} - k_{2p^2_{NH_3}}/p^3_{H_2}}{\left(p^2_{NH_3}/p^2_{H_2} + C_{p_{H_2O}/p_{H_2}}\right)^{1/2}}$$

and found the values of *C* listed in Table 19.

Table 19. *C* values for the ammonia synthesis rate equation

Catalyst	Temperature, °C				
	400	425	450	475	500
Fe + Al_2O_3	0.63	0.39	0.24	0.17	0.12
Fe + Al_2O_3 + K_2O	0.74	0.46	0.28	0.20	0.14

A more recent investigation [374], [375], [376] proposed multiplying the rate equation by a correction factor 1 – Θ, where $\Theta = a + bT + cT \ln X_{H_2O}$ and X_{H_2O} is the molar fraction of H_2O. Some authors assume a different route for the formation of adsorbed atomic oxygen [377], [378]:

$$H_2O(g) + 3* \rightleftharpoons 2\,H* + O*$$

where * denotes a surface site.

The equivalence of H_2O, CO, CO_2 and O_2 [379] with respect to their poisoning effect has been confirmed.

The experimentally determined effect of water vapor concentrations up to about 30 ppm on the activity of a commercial catalyst (BASF S 6–10) at 30 MPa is evident from Figure 23.

Figure 23. Reversible effect of increasing water vapor concentrations in the synthesis gas on the activity of industrial ammonia catalysts

With continuing exposure oxygen compounds also cause irreversible damage to the catalyst activity that is causally linked with growth of the iron primary crystallite [376], [380]. This is probably one of the main causes of the decline in converter performance over the course of the catalyst operating life. This damage depends on the water-vapor partial pressure and is especially serious, in contrast to reversible poisoning, at high temperatures. In a pilot plant, Österreichische Stickstoffwerke (ÖSW), Linz, established that at 30 MPa and a water-vapor content of 250 ppm, for example, the production declined by about 15 % per month. For a carbon monoxide content of 5 ppm, they determined about a 4 – 5 % decrease in activity per year. The influence of the operating temperature is evident from the data. The performance of a catalyst operated at 570 °C is about 35 – 40 % under that of a catalyst charge operated at 520 °C. That is, the higher the temperature, the greater is the harmful effect of oxygen compounds [381]. Corresponding to the data, they established that above all, temperatures above 500 – 520 °C must be avoided in order to achieve a converter charge operating period of more than 2 – 3 years. If the temperature is kept at this level, generally recommended for modern plants, then even at CO concentrations of 20 ppm in the recycle loop gas, no serious deterioration of the catalyst performance is observed after a month of operation. With the highly purified synthesis gas of modern synthesis processes (with final gas purification by methanation the carbon monoxide level is lowered to below 5 ppm), operating periods of up to 14 years can be achieved for a converter charge without significant loss of activity (Fig. 24).

Figure 24. Activity of BASF ammonia catalyst S 6–10 in a commercial converter after 14 years of operation

• fresh catalyst; △ after 14 years operation

As already mentioned in Section Composition, the concentration and combination of promoters affect the degree of irreversible damage. This must be considered in the choice of catalyst for a particular plant.

Sulfur, Phosphorus, and Arsenic Compounds. Sulfur, occasionally present in synthesis gases from coal or heavy fuel oil, is more tightly bound on iron catalysts than oxygen. For example, catalysts partially poisoned with hydrogen sulfide cannot be regenerated under the conditions of industrial ammonia synthesis. Compounds of phosphorus and arsenic are poisons but are not generally present in industrial syngas. There are indications that these permanent poisons exert the most detrimental effect when present as hydrogen compounds and are less harmful in higher oxidation states [382].

With regard to the sulfur bound on the catalyst surface, differences exist between the various types of ammonia catalysts, especially between those containing or free of alkali and alkaline earths. Pure iron and catalysts activated simply with alumina chemisorb S_2N_2 or thiophene when treated with concentrations of H_2S that lie below the equilibrium for the FeS bond, a maximum of 0.5 mg of sulfur per m^2 of inner surface or free iron surface; this corresponds to monomolecular coverage [383], [384]. The monolayer is also preserved on reduction with hydrogen at 620 °C, whereas FeS formed by treatment above 300 °C with high H_2S concentrations is reducible as far as the monolayer. For total poisoning, 0.16 – 0.25 mg S/m^2 is sufficient. Like oxygen, sulfur promotes recrystallization of the primary iron particle.

Under similar poisoning conditions, alkali- and alkaline earth-containing industrial catalysts adsorb more H_2S. In spite of this, however, in terms of activity, they are more stable toward the action of sulfur and are partially regenerable [384]. In a catalyst bed, most of the sulfur already has been taken up in the gas inlet layer. A catalyst sulfur content of several 100 ppm suffices to impair its activity [14].

In industrial plants, sulfur may reach the ammonia converter in various forms. In some plants, traces of H_2S and COS may not be removed in the upstream purification steps and so may enter the converter with the make-up gas. However, the sulfur contained in the compressor oil constitutes the main danger. On cracking the oil to lower molecular mass hydrocarbons, sulfur is freed as H_2S. It is therefore very important to use an oil with low sulfur content in ammonia plants, especially those still using reciprocating compressors. If after mixing with the recycle gas the make-up gas first runs through an ammonia condensation stage in which the H_2S and also to a certain extent COS are very effectively washed out by condensing ammonia, a sulfur content of the oil of 0.1 – 0.2 wt % ought to be sufficiently low. Otherwise, a value under 0.1 % is recommended [385]. In modern plants designed with centrifugal compressors and in which the sulfur content of the synthesis gas is extremely low because of very effective purification (about 0.5 – 1 µg S/m^3 (STP)), sulfur poisoning is of lesser importance than carbon monoxide and chlorine poisoning.

Chlorine compounds. The permanent poisoning effect of chlorine compounds is two orders of magnitude worse than that of oxygen compounds. Concentrations of about 0.1 ppm are viewed as the uppermost allowable limit in order not to affect adversely the life of ammonia catalysts [385]. The deactivation effect is based at least in part on the formation of alkali chlorides that are volatile at the upper synthesis temperatures.

Further information on catalyst poisoning is given in [375], [376].

4.4.2. *Other Catalysts*

4.4.2.1. *General Aspects*

For a long time efforts to improve the efficiency of industrial ammonia production concentrated on synthesis gas production, and major progress was achieved over the years. In ammonia synthesis itself considerable progress was made in converter design and recovery of the reaction energy at high temperature, but there has been no substantial improvement in the catalyst since the 1920s. The standard commercial iron catalyst still requires relatively high pressures (usually in excess of 130 bar), high temperatures (400 – 500 °C) and large reactor volumes (more than 60 m^3 for a capacity of 1500 t/d) to achieve good economics, although in a few cases a pressure as low as 80 bar has been used. From the vast amount of experimental and theoretical studies of the iron catalyst one can conclude that there is only limited potential for further improvement. Substantial energy savings would require lowering the synthesis pressure considerably, down to the synthesis gas production level, say. However, to compensate for the less favorable equilibrium situation much lower operating temperatures would be necessary, because otherwise too low an ammonia concentration would result, and additional energy would be needed for recovery, thus cancelling the energy saving from synthesis gas compression. To reach this goal a synthesis catalyst with a volumetric efficiency some two orders of magnitude greater than magnetite would be necessary. Process studies show an energy saving potential of about 1 GJ per tonne NH_3 [1279].

In the search for an alternative catalyst, most metals have been tested, either as primary components or as promoters. Much of this work was performed in the early, pioneering studies in the BASF laboratories [250], [251]. Most of the studies in the following years concentrated on the magnetite system in the sense of more fundamental and general catalytic research. Rising energy costs since the mid-1960s have given a new incentive to the search for other catalyst systems with improved performance. The first development which found commercial application was a cobalt-modified magnetite catalyst introduced in 1984 by ICI. With similar kinetic characteristics its volumetric activity is about twice that of the standard iron catalyst. The only other catalyst system which exhibits a promising potential for industrial application is based on ruthenium [195]. These new efforts to find improved catalysts could use methods and knowledge of modern surface science as developed on the example of the magnetite catalyst. Structural sensitivity and nature of the nitrogen adsorption and dissociation steps could serve as guidelines [196].

For the overall performance of potential catalysts in practical application additional factors, such as number of active sites, physical form, and porosity must also be taken into account. The classical commercial iron catalyst is an unsupported catalyst. First of all iron is a cheap material and secondly by the incorporation of alumina a surface area similar to that attained in highly dispersed supported catalysts can be obtained. Of course, for an expensive material such as the platinum group metals, the use of a support material is the only viable option. The properties of the supported catalyst will be influenced by several factors [195]

– Adequate surface of the carrier to achieve a reasonable metal loading.

- Dispersion stability by using a more active support with strong interaction between the support phase and the metal precursor. Too strong an interaction may cause difficulties in the metal reducing.
- Promoter localization with respect to metal sites and support sites.
- Gas transport effects will be governed by pore size, pore distribution, and tortuosity.
- Anion retention capability, which plays a role in the catalyst preparation by impregnation of a support with metal impregnation of the support.

4.4.2.2. *Metals with Catalytic Potential*

Materials that show significant ammonia synthesis activity can be divided into three categories according to their ability to form nitrides:

1. Platinum group metals: no stable nitrides (Ru, Os, Ir, Pt)
2. Metals forming nitrides unstable under reaction conditions (Mn, Fe, Co, Ni, Tc, Re)
3. Metals likely to be present as nitrides under synthesis conditions (groups 3 – 6 of the periodic table)

Of the platinum group metals only ruthenium and osmium show an activity superior to iron, though only in presence of alkali metal promoters, as may be seen from Table 20[386].

Table 20. Ammonia synthesis activity of metals supported on carbon with potassium metal promotion (mL NH_3/ mL catalyst, 573 K, 128.313 kPa, H:N = 3:1)

	Fe 0.72	Co 0.4	Ni 0.04	
Mo 0.6	Ru 22.2	Rh 0.52	Pd 0	
Re 0.36	Os 5.6	Ir 0.68	Pt 0.008	

Although osmium was the first active catalyst used by HABER in 1909 [387] in his laboratory-scale unit to demonstrate the technical viability of the high-pressure recycle process, this metal never became an industrial catalyst because of its limited availability and its dangerous properties. The interest therefore shifted to ruthenium. The most active ruthenium catalysts use a graphite support and alkali metal promotion, preferentially with rubidium or cesium [394], [398]. It is unlikely that the promoter is in metallic state as its high vapor pressure would probably lead to substantial losses under synthesis conditions. It is assumed that a charge transfer complex $M^{+}\cdots C^{-}$ is formed between the metal and the graphite. A major advantage of graphite is its ability to stabilize high loadings of alkali metals. A special limitation until recently was the chemical reactivity of carbon supports. In a typical ammonia synthesis environment with high hydrogen partial pressure, the catalyst may also catalyze the methanization of carbon, which would lead to destruction of the support. Indeed, this phenomenon has been observed [388], but it can be avoided by careful heat treatment of the support above 1500 °C [389]. With this modified carbon material lifetimes of at least six years are expected [386].

The group of metals forming low-stability or unstable nitrides includes Mn, Fe, Co, Ni, Tc, and Re. As in the case of iron a clear structural sensitivity was found for rhenium but the role of promoters remains the subject of discussion. There are also indications of structure sensitivity for cobalt and nickel. It was attempted to improve the activity of the classical magnetite catalyst by alloying with nickel or cobalt. The only commercial catalyst is a cobalt containing magnetite [390].

Of the group of metals forming stable nitrides, only molybdenum is of some interest. Under synthesis conditions it is present as a nitride with some ammonia formation activity and structural sensitivity [391]. Molybdenum also seems to exhibit activity in biological nitrogen fixation [392] and is synthetically active at ambient conditions in the air-sensitive Glemser compounds [392], [393].

The results of the intensive research in this field over the last decades demonstrate that, irrespective of the catalyst, the rate-determining step in the ammonia synthesis reaction is the dissociation of the nitrogen molecule and the catalyst effectivity is determined in the first instance by the activation energy of the dissociation reaction. The other common factor for the ammonia catalysis is the structure sensitivity of molecular nitrogen adsorption. Only if both conditions are favorable, and other factors such as hydrogen and ammonia inhibition do not play a major role, can a sufficient overall reaction rate be expected. The available data show that these conditions are fulfilled only for a limited number of metals: iron, ruthenium, and osmium. On account of its very strong ammonia inhibition rhenium is not an option. Extensive literature on non-iron catalysts is given in [195], [196]; kinetic investigations are reported in [196].

4.4.2.3. *Commercial Ruthenium Catalysts*

Since the early days of industrial ammonia synthesis only minor improvements have been achieved for the magnetite system: optimization of manufacturing procedures, promoter concentrations, and particle size to give somewhat higher activity and longer service life.

A notable development for the magnetite system was the introduction of cobalt as an additional component by ICI in 1984 [395], [396]. The cobalt-enhanced catalyst formula was first used in an ammonia plant in Canada using ICI Catalco's AMV process (later also in other AMV license plants) and is also successfully applied in ICI's LCA plants in Severnside. Commercially successful is a new type of iron-based catalyst, the AmonMax-10 of Südchemie which uses wustite instead of magnetite. This catalyst is already used in seven ammonia plants with a total capacity of 5600 t/d [1320-1322], [1410]. Production of synthetic wustite is described in [1324], its application for ammonia synthesis catalyst in [1323]. For a literature report on promoted iron catalysts see [1325].

In 1979 BP disclosed to M.W. Kellogg a new catalyst composed of ruthenium on a graphite support [395], [397]. In October 1990, after a ten-year test program, Kellogg started the commercialization of the Kellogg Advanced Ammonia Process (KAAP) using this catalyst [397], which is claimed to be 10 – 20 times as active as the traditional iron catalyst: The KAAP catalyst. According to the patent [390] the new catalyst is prepared by subliming ruthenium-carbonyl $[Ru_3(CO)_{12}]$ onto a carbon-containing support which is impregnated with rubidium nitrate. The catalyst has a considerably higher surface area than the conventional catalyst and, according to the patent example, it should contain 5 wt % Ru and 10 wt % Rb. Besides having a substantially higher volumetric activity, the promoted ruthenium catalyst works best at a lower than stoichoimetric H/N ratio of the feed gas as shown in Figure 25. It is also less susceptible to self-inhibition by NH_3 (Figure 26) and has excellent low-pressure activity.

Figure 25. Effect of H/N ratio on activity of Ru and Fe_3O_4 catalysts [195]

Figure 26. Ammonia inhibition of Ru and Fe_3O_4 catalysts [195]

Three ammonia plants in Trinidad, each with a nameplate capacity of 1850 t/d, use the KAAP ruthenium catalyst [1317]. The first layer of the four-bed reactor [1318], [406] is loaded with conventional magnetite catalyst, the others with the ruthenium – graphite catalyst. For the special properties of ruthenium, which have to be considered in handling these catalysts see [406]. Topsøe has developed a ruthenum catalyst which uses boron nitride instead of graphite as support. Boron nitride, occasionally called “white graphite”, because of its structure similar to graphite, is completely stable towards hydrogenation under all conditions relevant to technical ammonia synthesis. A Ba-Ru/BN catalyst proved completely stable in a 5000 h test at 100 bar and 550 °C using a 3:1 H_2 – N_2 mixture [1326]. There is no industrial

application so far. A discussion on ruthenium as ammonia synthesis catalyst with an extensive literature review is found in [1389].

The potential for ruthenium to displace in the long run iron in new plants will depend on whether the benefits of its use are sufficient to compensate the higher costs. Ruthenium prices increased by a factor of four in 2000 to 170 $/oz. due to new applications in the electronic industry. Ruthenium price development is occasionaly published in FINDS, a Stokes Engineering Publication.

In common with the iron catalyst ruthenium will also be poisoned by oxygen compounds. Even with some further potential improvements it seems unlikely to reach an activity level which is sufficiently high at low temperature to allow operation of the ammonia synthesis loop at the pressure level of the syngas generation. An overview over ammonia synthesis catalyst development history and newer research is given in [1326].

4.5. Process Steps of Ammonia Production

The term “ammonia synthesis” is increasingly used when referring to the total ammonia production process. Synthesis conditions are no longer viewed in isolation. Of course, they are an important consideration in the total process but can be determined properly only in relation to the total plant integration (see Section Complete Ammonia Production Plants). A literature summary of ammonia production is contained in [402] and [403]; the United States patent literature in the field from 1972 to 1980 is covered in [304]. More modern and comprehensive reviews of ammonia production technology can be found in [404-406], [1318], [1132]. The journal *Nitrogen*, now named *Nitrogen + Syngas*, published by British Sulphur, presents an update of the state of the art from time to time.

The complete process of industrial ammonia production may be subdivided into the following sections:

A. Synthesis gas production
   1. Feedstock pretreatment and gas generation
   2. Carbon monoxide conversion
   3. Gas purification
B. Compression
C. Synthesis and purge gas management

The most fundamental changes over the years have occurred in synthesis gas production and gas compression. In the synthesis section itself, some progress has been made in converter design and optimization of heat recovery.

Synthesis gas preparation, carbon monoxide conversion, and gas purification for ammonia synthesis are treated in detail in the article ⟶ Gas Production. Therefore, only a short abstract is presented here.

4.5.1. *Synthesis Gas Production*

The goal is preparing a pure mixture of nitrogen and hydrogen in the stoichiometric ratio of 1 : 3. The raw materials are water, air, and a carbon-containing reducing medium, that, for its part, may contain hydrogen (natural gas, CH_4 ; naphtha, ≈ CH_2; petroleum, ≈ CH) and nitrogen; for example, natural gas from the Slochteren field in the Netherlands contains 14 % nitrogen.

Usually only the carbon-containing materials and hydrogen from other sources are regarded as raw materials in the narrow sense because of the abundance of air, which provides all of the nitrogen, and water, which generally supplies most of the hydrogen. The term feedstock is often applied to the total consumption of fossil fuel, although strictly speaking a distinction should be made between gasification feed and fuel for energy generation.

Certain raw materials for synthesis gas production that were once of primary importance currently are used only under special economic and geographical circumstances (e.g., China, where 66 % of production is based on coal). These include solid fuels, coke oven gas, and hydrogen produced by electrolysis. Reference [409] covers coke oven gas as a feedstock for ammonia synthesis and references [410-413] describe producing hydrogen by water electrolysis for ammonia production.

Table 21 provides an overview of the raw material sources (apart from water and air) for world ammonia capacity.

Table 21. Feedstock distribution of world ammonia production capacity

	1962		1972		1983		1998	
	10^3 t N	%	10^3 t N	%	10^3 t N	%	10^3 t N	%
Coke oven gas and coal	2800	18	4600	9	7200	8	16500	14
Natural gas	7800	50	32100	63	66850	74	94300	77
Naphtha	2050	13	10700	21	9050	10	7300	6
Other petroleum products	2950	19	3600	7	7200	8	4400	3
Total	**15600**	**100**	**51000**	**100**	**90300**	**100**	**122500**	**100**

Table 21 indicates that new ammonia plants are based almost exclusively on natural gas and naphtha. This trend is also expected to continue in the near future. Naturally, the regional distribution is diverse. In North America, for example, natural gas dominates, with 95 % of capacity. In the EU, 86 % of capacity is based on natural gas and 8 % on naphtha [502].

The capital cost and the specific energy requirement (i.e., feed and fuel, and so the manufacturing cost) largely depend on the raw material employed [414], [415]. Table 22 shows the relative capital cost and the relative energy requirement for a plant with a capacity of 1800 t/d ammonia. For the natural gas based plant the current best value of 28 GJ per tonne NH_3 is used. If water electrolysis (4.5 kWh/Nm^3 H_2) is used together with an air separation unit for the nitrogen supply the energy requirement amounts to 34 GJ per tonne NH_3 when the electric energy is valuated just with the caloric equivalent, which would be only justified when electric power is generated from water power. In case of electricty generation from fossil energy with 40 % efficiency the consumption figure is 85 GJ per tonne NH3, which is 300 % of the consumption of a modern steam reforming plant [1364]. The investment could according to a rather rough estimate be about three times the investment for a steam reforming plant with natural gas.

Table 22. Relative ammonia plant investment and relative energy requirement for 1800 t/d NH_3

	Natural gas	Naphtha	Fuel oil	Coal
Relative investment	1.0	1.15	1.5	2.5
Relative specific energy requirement (based on lower heating values)	1.0	1.1	1.3	1.6

4.5.1.1. *Feedstock Pretreatment and Raw Gas Production*

The chemical reaction of hydrocarbons with water, oxygen, air, or any combination of these is generally referred to as gasification. It yields a gas mixture made up of CO and H_2 in various proportions along with carbon dioxide and, where air is used, some nitrogen. Any carbon containing feedstock will undergo a reaction according to Equation (5) or (6) or both simultaneously.

$$[CH_x] + H_2O \rightleftharpoons CO + H_2 + x/2\,H_2 \Delta H > 0 \quad (5)$$

$$[CH_x] + 1/2\,O_2 \rightleftharpoons CO + x/2\,H_2 \quad \Delta H < 0 \tag{6}$$

Light hydrocarbons ranging from natural gas (methane) to naphtha (max. C_{11}) undergo reaction with steam over a catalyst according to Equation (5) which is usually called steam reforming. Corresponding to Equation (6), commonly known as partial oxidation, all carbon-containing feedstocks can be processed in a noncatalytic reaction with oxygen (together with a minor amount of steam for process reasons, which gives rise to a simultaneous reaction according to Eq. 5). An additional equilibrium reaction involved in any gasification process is the water gas shift reaction (7).

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \Delta H^0_{298} = -41\ \mathrm{kJ/mol} \tag{7}$$

Although reaction in the right hand direction is favored by lower temperatures it is responsible for the initial carbon dioxide content of the raw synthesis gas. To maximize the hydrogen yield, this reaction is carried out in a separate step over a different catalyst at a lower temperature than the preceding gasification step (Section Carbon Monoxide Shift Conversion).

From Equation (5) it can be seen that in the steam reforming variant the proportion of hydrogen supplied by the feedstock itself increases with its hydrogen content. It attains the theoretical maximum of 66 % with methane. The hydrogen – oxygen bond energy in water is higher than the hydrogen – carbon bond energy in the hydrocarbon. The positive enthalpy per mole of hydrogen therefore decreases as the proportion of hydrogen contributed from the feedstock itself increases. Natural gas consists predominantly of methane and is therefore the most hydrogen-rich and energetically the best raw material for the steam-reforming route. In the partial-oxidation route less hydrogen is produced in the primary gasification step and the raw synthesis gas has a rather high CO content.

The raw gas composition is thus strongly influenced by the feedstock and the technology applied. But for the different feedstocks there are some constraints on the applicability of the various gas generation processes. The catalytic steam reforming technology can only be applied to light hydrocarbon feedstock (up to naphtha) but not for heavy hydrocarbons such as fuel oil or vacuum residue. These raw materials contain a substantial amount of sulfur and also minor quantities of heavy metals, which would poison the sensitive reforming catalyst. In addition cracking reactions will occur on the catalyst, depositing carbon, which not only blocks the catalyst pores but also restricts interparticle flow. Thus for heavy feedstocks the only choice is noncatalytic partial oxidation, which, however, is capable of processing any type of hydrocarbon feedstock. The various commercial coal gasification processes may also be classified as partial oxidations.

Steam Reforming Processes. (see also ⟶ Gas Production – Steam Reforming of Natural Gas and Other Hydrocarbons). As the nickel-containing catalysts are sensitive to poisons, any sulfur compounds present in the hydrocarbon feedstock have to be removed by hydrodesulfurization, generally with a combination of cobalt – molybdenum and zinc oxide catalysts [560], [561], [639].

Adsorption on activated carbon is an alternative when the feed is natural gas with a rather low sulfur content.

$$R - SH + H_2 \rightarrow RH + H_2S \tag{8}$$

$$H_2S + ZnO \rightarrow ZnS + H_2O \tag{9}$$

The general overall reaction can be formulated as

$$C_nH_{(2^n+2)} + n\,H_2O \rightleftharpoons nCO + (2n+1)H_2 \tag{10}$$

or more specifically for methane, usually the major constituent of natural gas, as:

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2 \quad \Delta H = +206\ \mathrm{kJ/mol} \tag{11}$$

Simultaneously to this equilibrium the water gas shift reaction (Eq. 7) proceeds.

To introduce nitrogen to achieve the required stoichiometric hydrogen/nitrogen ratio for ammonia synthesis, the reforming reaction is split into two sections. In the first section, the primary reformer, the reaction proceeds in indirectly heated tubes filled with nickel-containing reforming catalyst and is controlled to achieve a partial conversion only [in conventional plants 65 % based on methane feed, leaving around 14 mol % methane (dry basis) in the effluent gas]. In the following secondary reformer — a refractory-lined vessel filled with nickel catalyst — the gas is mixed with a controlled amount of air introduced through a nozzle (burner). By combustion of a quantity of the gas the temperature is raised sufficiently (to about 1200 °C) that the endothermic reforming reaction is completed with the gas adiabatically passing the catalyst layer. In this way the outlet temperature is lowered to around 1000 °C, and a residual methane content of 0.5 % or lower (dry basis) is attained in conventional plants [404, 406]. Nitrogen already present in the natural gas tends to cause a reduced specific air ratio in the secondary reformer and a reduced secondary reformer temperature rise. Therefore, to maintain the same methane leak, the primary reformer exit temperature must be increased.

The primary reformer consists of a multitude of reformer tubes loaded with the nickel catalyst (15 – 25 % NiO on α-aluminum oxide, calcium aluminate, or magnesium aluminum spinel support) [1318] in a furnace box in which the heat needed for the reaction is transferred to the tubes by radiation. The heat is generated in burners, generally gas-fired, in the furnace box.

A special consideration is the lifetime of the expensive reformer tubes, made of highly alloyed chromium-nickel steel by centrifugal casting, because under the severe reaction conditions the material exhibits creep which finally leads to rupture [1327], [1390]. The time to rupture for a specific material depends on the tube-wall temperature and on the internal pressure. This limits the reforming pressure, which to save energy in synthesis-gas compression should be as high as possible. As the reforming reaction is endothermic and proceeds with volume increase the negative effect of a pressure increase (lower conversion) has to be compensated by a higher reaction temperature and hence higher wall temperatures, but this is limited by the material. Another possibility to compensate is a higher steam surplus (steam/carbon ratio), but this is economically unfavorable. The furnace box usually accommodates 200 – 400 tubes (depending on plant capacity), 10 – 13 m long, with an inner diameter of 75 – 140 mm and a wall thickness of 11 – 18 mm. The standard material for a long time was HK 40 (20 Ni/25 Cr) but for replacements and new plants, HP modified (32 – 35 Ni/23 – 27 Cr stabilized with about 1.5 % Nb) is being increasingly used on account of its superior high-temperature properties [425]. With this latter tube material a reforming pressure of 40 bar is possible at outer tube-wall temperatures of around 900 °C . A further improvement are *microalloys* that additionally contain Ti and Zr [406], [1318], [1373], [1376].

According to the disposition of the burners primary reformers can be classified as top-fired, side-fired, terraced-wall, or, less common, bottom-fired reformers [406], [1318]. The steam/carbon ratio used in modern commercial primary reformers for natural gas is between 2.8 and 3.5, and markedly higher for naphtha, for which an alkalized nickel catalyst has to be used to prevent carbon deposition, which causes catalyst deactivation and local overheating of tubes (hot bands and hot spots). A special requirement for the catalyst is a low content of silica, which could be volatile under the hydrothermal conditions and deposit downstream of the secondary reformer at lower temperature, causing fouling of the waste-heat recovery surfaces.

When higher hydrocarbons (naphtha) are used, a so-called “rich gas stage” can be utilized upstream of the primary reformer. In this, the higher hydrocarbon – steam mixture is transformed at relatively low temperature (400 – 500 °C) and steam – carbon ratios less than two into a methane-rich gas. This is then converted in the primary reformer under normal reforming conditions. For this rich-gas stage, three processes are commercially available: the British Gas Process [426], the BASF – Lurgi Process [427-429], and the Japan Gasoline Process [430].

This process has recently become the subject of renewed interest for increasing the capacity of existing natural-gas-based ammonia plants in which the primary reformer has been identified as bottle-neck. Under the name pre-reforming, it is installed up-stream of an existing tubular reformer [431-438], [406], [1318]. The natural gas enters such a pre-reformer with a temperature of 530 °C instead of being fed to the primary reformer tubes with the same temperature. A temperature drop of about 60 – 70 °C occurs in the catalyst bed due to the overall endothermic reaction. Medium-grade heat is used to reheat the exit gas to the correct primary reformer entrance temperature. This compensation heat may be derived from a variety of sources, including flue gas, process gas, or gas turbine exhaust.

Another possibility for reducing the load on the primary reformer is to transfer part of the conversion duty to the secondary reformer with application of an super-stoichiometric amount of air. This requires removal of the surplus of nitrogen from the synthesis gas either ahead of the synthesis loop (by cryogenic methods or pressure swing adsorption) or by purge gas and hydrogen recovery [457], [458]. In the extreme case the whole reforming reaction could be performed without a tubular reformer by autothermal catalytic reforming in a design similar to a secondary reformer. In this case it would be necessary to use oxygen or oxygen-enriched air instead of air [404], [446], [459], [460], [1318], [1413, 1414]. Unlike to a secondary reformer, which is fed with partially reformed gas, having a substantial concentration of hydrogen, the autothermal reformer (ATR) is fed directly with the hydrocarbon feedstock. Because of the higher heat of reaction in the internal combustion (temperature >2000 C), the flow conditions, heat release characteristics and the risk of soot formation are very different from the situation of a normal secondary reformer. Therefore special considerations in the design of burner and reactor are necessary. See also ⟶ Gas Production.

A recent development which avoids a fired primary reformer is the exchanger reformer, which with some simplification may be viewed as tubular heat exchanger with

the catalyst inside the tubes, which are heated by the hot secondary reformer effluent flowing on the shell-side. In some designs the tubes may be open at the lower end, in which case the gas flow on the shell side consists of a mixture of the off-gases from the secondary reformer and from the reformer tubes. Commercially operating designs are the GHR of ICI (Figure 27) [406], [461-464] and the KRES of M. W. Kellogg [466-470], [1318-1320], [1398] (Fig. 28). Similar concepts are offered by other licensors and contractors e.g., Braun & Root, or Topsøe [406].

Figure 27. ICI gas heated reformer

A) GHR; B) AGHR

a) Tubeside inlet; b) Tubeside outlet; c) Scabbard tube; d) Bayonet tube; e) Sheath tube; f) Shellside inlet; g) Shellside outlet; h) Catalyst tube; i) Seal; j) Tail pipe; k) Catalyst; l) Refractory lining

ICI has come out with a modified design, the AGHR, with “A” standing for advanced. As shown in Figure 27 B, the bayonet tubes are replaced by normal tubes attached to a bottom tubesheet using a special seal to allow some expansion. In this way the delicate double tubesheet of the GHR is avoided. The seal which prevents leakage of methane-rich gas to the secondary reformer effluent flowing on the shell side has a unique design which is subject to patent applications of ICI. The AGHR will allow a single-line concept for worldscale plants whereas with the GHR several parallel units for large plants would be necessary [406].

Figure 28. Kellogg reforming exchanger System (KRES) [406]

Because of the smaller size compared to a conventional fired reformer considerable investment savings can be achieved. To close the heat balance between the exchanger reformer and secondary (autothermal) reformer, the latter has to take on a higher reforming duty, which may be achieved by using an over-stoichiometric amount of air or oxygen-enriched air. In some configurations the exchanger reformer is partially by-passed, part of the feed being fed directly into the autothermal reformer.

Haldor Topsøe has developed an exchanger reformer called HTER which may be used in various process configurations as described in [1328]. The design may be also used as a convective reformer, called HTCR with a dedicated burner.

A concept developed by Uhde goes a step further in this direction: exchanger reforming and subsequent noncatalytic partial oxidation, which provides the reaction heat, are accommodated in a single vessel. This combined autothermal reformer (CAR) design, shown in Figure 29 was operated in a demonstration unit producing 13 000 m^3/h of synthesis gas [472-475].

Figure 29. Uhde combined autothermal reformer (CAR)

a) Sandwich type tubesheet; b) Enveloping tube; c) Reformer tubes; d) Tubesheet; e) Refractory lining; f) Water jacket

A unique steam reforming process [439-441] has been developed in Japan to the pilot-plant stage. It reportedly can operate without upstream desulfurization and should be able to gasify naphtha, crude oil, and atmospheric or vacuum residues.

For literature on steam reforming see [404-408], [420], [442-448]; reaction kinetics and thermodynamics [1318]; for steam reforming of naphtha, [451-453]; for steam reforming catalysts, [454], [455], [406], [456], [1318], [1331] for reformer design, [406], [449, 450], [1318]. An oververview of the steam reforming technology, its historical development, present state of the art, newer developments and future perspectives together with quotation of newest literature is given in [1327]. Detailed discussion on exchanger reforming and autothermal reforming is found in [1328].

Partial Oxidation. Hydrocarbons or coal will react with an amount of oxygen insufficient for total combustion to CO_2 according to:

$$C_nH_m + n/2\,O_2 \rightarrow n\,CO + m/2\,H_2 \tag{12}$$

$$C + 1/2\,O_2 \rightarrow CO \quad \Delta H = -123\,kJ/mol \tag{13}$$

In practical operation some steam must always be added, the quantity depending on feedstock and process configuration, so that the following reactions proceed in parallel:

$$C_nH_m + n\,H_2O \rightarrow n\,CO + (n + m/2)H_2 \tag{14}$$

$$C + H_2O \rightarrow CO + H_2 \quad \Delta H = +119\,kJ/mol \tag{15}$$

As the overall reaction is exothermic no external heat supply is necessary. Since in some processes with coal feedstock (e.g., the Lurgi Process) the reaction according to Equation (15) may proceed to a considerable extent, they are more often referred to as coal gasification rather than as partial oxidation, but this is just a matter of definition.

Certain processes have achieved particular significance. The Texaco and Shell processes can handle fuel oil, vacuum residues, and coal. The Lurgi process handles lump coal, operates at 2.5 MPa, the Koppers – Totzek process operates on coal dust at atmospheric pressure.

Partial Oxidation of Hydrocarbons. The two dominant processes are the Texaco Syngas Generation Process (TSGP) and the Shell Gasification Process (SGP). In both the reaction is performed in an empty pressure vessel lined with alumina. The reactants (oil and oxygen, along with a small amount of steam) are introduced through a nozzle at the top of the generator vessel. The nozzle consists of concentric pipes so that the reactants are fed separately and react only after mixing at the burner tip or in the space below. The temperature in the generator is between 1200 and 1400 °C. Owing to insufficient mixing with oxygen, about 2 % of the hydrocarbon feed is transformed into soot, which is removed from the gas by water scrubbing. Depending on the process configuration the gas is either cooled by quenching or in a waste-heat boiler. The TSGP and SGP are rather similar, they mainly differ in the nozzle design, soot removal and recirculation, and process gas cooling. The reaction pressures may be as high as 80 bar; there are no mechanical or material limitations to raising the gasification pressure further, but with respect to the overall ammonia process this might be beyond the energy optimum because of the increasing energy demand for nitrogen and oxygen compression. Maximum raw gas generation capacity of a single generator corresponds to about 1000 t/d ammonia. World-scale ammonia plants based on partial oxidation exist in Germany, India, China, and other countries [465]. Further information is found for the TSGP in [421-424], [486], [487, 489-491], for the SGP in [471], [477-485], [492]; see also ⟶ Gas Production – Partial Oxidation of Hydrocarbons.

Partial Oxidation of Coal. So far the Koppers – Totzek, Texaco and Lurgi gasifiers, and probably the Winkler process in some smaller installations, have been used in ammonia plants, but the successful demonstration of the Shell process in other applications makes it a potential candidate for ammonia production, too. Additional processes in different stages of technical development are the HTW and the Dow process. Information on the status and the development in the gasification of coal can be obtained from [493-496], [498-501], [503]. A special case is China, where a number of small plants with a capacity of 30 – 80 t/d still produce their synthesis gas with the today largely outdated water-gas process which operates at atmospheric pressure. Coke or anthracite is reacted intermittently with air and steam in a fixed bed. The heat produced by the exothermic reaction of coal and air in the “blow phase” is stored in the fixed bed and provides the heat needed for reaction of coal with steam in the “run phase” [99], [497].

The Koppers – Totzek Process [504], [506-509], [510] used in several ammonia plants in China, India, and South Africa, operates practically at atmospheric pressure. Dry coal dust is fed to the two (sometimes four) burners of the gasifier. Oxygen, together with a small amount of steam, is introduced immediately at the head of the burners, and the mixture enters the reaction zone with high velocity. The residence time is less than 1 s and the temperature is 1500 – 1600 °C. The gas leaving the top of the reactor vessel is cooled in a waste-heat boiler, followed by a water scrubber to remove carbon and ash traces from the raw gas and to effect further cooling. Liquid slag is withdrawn from the reactor bottom. The process can handle bituminous coal and lignite. To overcome the disadvantage of atmospheric pressure operation, a version was developed capable of operating at 25 – 30 bar. This Prenflow (pressurized entrained flow) process [511], [1132] is being tested in a 48 t/d pilot plant.

The Texaco Coal Gasification Process [495], [518-525] is rather similar to the Texaco partial oxidation process for heavy hydrocarbons. An aqueous slurry containing 60 – 70 % coal is fed by reciprocating pumps to the generator at a pressure of 20 – 40 bar. Waste-heat boiler, quencher, and carbon scrubber are especially adapted to deal with the ash and slag introduced with the bituminous coal feed.

In its coal gasification process [495], [512-517]. Shell has completely departed from the concept of its process for partial oxidation of heavy hydrocarbons. With reversed flow pattern in the gasifier (from bottom to top), dry coal dust is introduced via lock hoppers into the reactor vessel operating at 20 – 40 bar.

The Lurgi Dry Gasifier [495], [526-530], [532], [533] performs the reaction in a moving bed, usually operating at 25 – 30 bar. Crushed coal with a particle size of 4 – 40 mm enters the top of the gasifier through a lock hopper and is evenly distributed over the cross-section of the coal bed surface by a distribution disk equipped with scraper arms. Ash with only 1 % of residual carbon is removed at the bottom of the gasifier by a revolving grid with slots through which steam and oxygen are introduced. The temperature in the lower section of the bed is around 1000 °C, and at the top where the raw gas exits about 600 °C. As a result of this lower temperature the raw gas has an increased content of impurities such as tars, phenols, and some higher hydrocarbons. In addition the methane content is relatively high (up to 10 – 15 %), so that purification and conditioning of the raw gas is a rather elaborate task. The process actually can use any sort of coal and can handle ash contents higher than 30 %. The British Gas/Lurgi Slagging Gasifier [495], [528], [531] operates without a grate with withdrawal of the liquid slag.

The classic Winkler gasifier, which operates at atmospheric pressure, is today still in use in some smaller plants (e.g., in China). In a further development (HTW process) by Rheinbraun it has been tested in a demonstration plant with lignite at 10 bar [534], [535].

The Advanced Coal Gasification Process (ACGP) [537], a new concept developed by AECI Engineering, Kynoch Ltd and Babcock Wilson, is an entrained gasification process at atmospheric pressure. Pulverized coal and oxygen are injected near the base of the gasifier through eight burners using a proprietary feed technique which employs a special pump. The gasifier is a slender column with a square cross-section. The combustion area is lined with heat resistant ceramic material. The upper part is made of finned tubes which are welded together and are circulated with water by thermosyphon action. So far no commercial installation exists but it is claimed that one unit can produce the synthesis gas for 750 t/d ammonia.

A block diagram showing steam reforming and partial oxidation together with the further steps needed to transform the raw gas into pure make-up gas for the synthesis is shown in Figure 30.

Figure 30. Alternative process steps for generation and purification of synthesis gas

4.5.1.2. *Carbon Monoxide Shift Conversion*

As ammonia synthesis needs only nitrogen and hydrogen, all carbon oxides must be removed from the raw synthesis gas of the gasification process. Depending on feedstock and process technology, this gas contains 10 – 50 % carbon monoxide and also varying amounts of carbon dioxide. In the water gas shift reaction, traditionally known as carbon monoxide shift conversion (Eq. 7), the carbon monoxide serves as reducing agent for water to yield hydrogen and carbon dioxide. In this way not only is the carbon monoxide converted to readily removable carbon dioxide but also additional hydrogen is produced:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \Delta H = -41.2\,\mathrm{kJ/mol} \tag{7}$$

As no volume change is associated with this reaction, it is practically independent of pressure, but as an exothermic process, it is favored by lower temperatures, which shift the equilibrium to the right-hand side. Even with a low excess of steam in the gas, the equilibrium concentrations of CO are low; for example, 0.2 vol % at 220 °C and 0.12 vol % at 200 °C for a steam/gas ratio of 0.4.

To keep the temperature low the heat of reaction must be removed in appropriate way and to achieve a sufficient reaction rate effective catalysts have to be applied. The process is therefore performed in steps, with intermediate heat removal between the individual catalyst beds in which the reaction runs adiabatically. Quasi-isothermal reactors have been developed in which cooling tubes run though the catalyst layers. As the process configuration and catalysts are to some extent different for steam reforming and partial oxidation, they are treated separately here.

Shift Conversion in Steam Reforming Plants. In the traditional plant concept, the gas from the secondary reformer, cooled by recovering the waste-heat for raising and superheating steam, enters the high-temperature shift (HTS) reactor loaded with an iron – chromium catalyst at 320 – 350 °C. After a temperature increase of around 50 – 70 °C (depending on initial CO concentration) and with a residual CO content of around 3 % the gas is then cooled to 200 – 210 °C for the low temperature shift (LTS), which is carried out on a copper – zinc – alumina catalyst in a downstream reaction vessel and achieves a carbon monoxide concentration of 0.1 – 0.3 vol %.

In the unreduced state the HTS catalyst is iron(III) oxide (Fe_2O_3) containing additionally 5 – 10 % chromic oxide (Cr_2O_3). During operation, it is reduced more or less stoichiometrically to the composition of magnetite (Fe_3O_4). This catalyst is active in the temperature rage of 300 – 500 °C. Steam surplus is not only necessary for thermodynamic reasons but also to suppress undesirable side reactions. Decreasing the steam surplus lowers the oxygen to carbon ratio in the HTS to such an extent that the atmosphere can reduce magnetite partially to metallic iron. In addition the Boudouard reaction can occur under these conditions. The resulting carbon is deposited within the catalyst particles causing their disintegration, and iron carbides will be formed, which are effective Fischer – Tropsch catalysts that lead to the formation of some methane and higher hydrocarbons [406], [544], [545]. Newly introduced HTS catalysts with additional copper promotion suppress this side reaction [546] and are therefore less sensitive to lower steam-to-gas ratios. The classical HTS iron catalyst is resistant against sulfur compounds, but this is of greater importance in partial oxidation processes and less for the practically sulfur-free steam reforming gas.

In some ammonia process schemes operating without a secondary reformer and applying pressure swing adsorption (PSA) for further purification (KTI PARC) only a HTS is used.

The LTS catalyst, supplied in pellets like the HTS catalyst, consists of 40 – 55 % copper oxide, 20 – 30 % zinc oxide, the balance being alumina. The catalyst properties are influenced far more by the formulation and manufacturing procedure [547] than by its chemical composition. The copper oxide is reduced in situ with hydrogen and a carrier gas (usually nitrogen) to form fine copper crystallites on which the activity depends. Sulfur, usually present as H_2S, has to be below 0.1 ppm, but even with such low concentrations, the catalyst is slowly poisoned. The ZnO adsorbs the sulfur and it finally transforms into bulk ZnS. When the ZnO is exhausted in a given layer of the catalyst, the H_2S causes deactivation of the copper by sintering. The poisoning process moves through the catalyst as a relatively sharp front and can be seen in the change of the catalyst temperature profile over time [548], [549]. The LTS catalyst is protected by a guard bed, formerly loaded with ZnO, but nowadays usually with LTS catalyst [558]. Changing the guard bed more frequently prolongs the service life of the main LTS catalyst bed. Traces of chlorine compounds [557], which may be introduced with the natural gas or more often with the process air to the secondary reformer, may also deactivate the LTS catalyst by accelerating the sintering of the copper particles. Unlike sulfur poisoning, chlorine is more diffusely distributed over the whole catalyst bed by migration as volatile zinc and copper chlorides.

As chemical composition and formulation of the LTS catalyst are very similar to methanol production catalysts, small quantities of methanol are formed and are found in the process condensate after cooling the LTS effluent. In a consecutive reaction, amines (mainly methylamine) are formed from the methanol and traces of ammonia originating from the secondary reformer and the HTS. These pollutants are removed from the process condensate by steam stripping and ion exchange. Byproduct formation is higher with fresh catalyst and declines with operating time. New catalyst types with increased activity and higher selectivity have reduced the problem. The tendency for methanol formation increases with decreasing steam/gas ratio [552].

A relatively new process concept is the intermediate temperature shift (ITS) [550] which performs the shift conversion in a single step. The catalyst is based on a copper – zinc – alumina formulation and optimized for operating in a wider temperature range than the standard LTS catalyst. The reaction heat can be removed by use of a tube-cooled reactor raising steam or heating water for gas saturation to supply process steam in the reforming section (Linde LAC, ICI Catalco LCA). In a new plant using the spiral-wound Linde reactor [551], a methane slip of only 0.7 mol % (dry basis) is achieved. Further purification is performed by PSA. Generally the shift conversion reactors have an axial gas flow pattern, but recently radial gas flow configurations have been chosen in some instances.

Additional literature on shift conversion can be found in [406-408], [418], [419], [536], [538-543], [404], [1318].

Shift Conversion in Partial Oxidation Plants. The raw synthesis gases from partial oxidation of heavy hydrocarbons and coal differ mainly in two aspects from that produced from light hydrocarbons by steam reforming. First, depending on the feedstock composition, the gas may contain a rather high amount of sulfur compounds (mainly H_2S with smaller quantities of COS); second, the CO content is much higher, in some cases in excess of 50 %. The sulfur compounds (see Section Gas Purification) can be removed ahead of the shift conversion to give a sulfur-free gas suitable for the classical iron HTS catalyst. In another process variant the sulfur compounds are removed after shift conversion, which thus has to deal with a high-sulfur gas. As the standard iron catalyst can tolerate only a limited amount of sulfur compounds, the so-called dirty shift catalyst is used in this case. This cobalt – molybdenum – alumina catalyst [417], [418], [554-556], [638] is present under reaction conditions in sulfidized form and requires for its performance a sulfur content in the gas in excess of 1 g S/m^3. Reaction temperatures are between 230 and 500 °C.

Irrespective of the catalyst type used, the high initial carbon monoxide concentration means that the reaction must generally be performed in steps, with intermediate cooling. It has been reported that the CO content can be reduced from 50 to 0.8 % in a single step in a large hydrogen plant by using a quasi-isothermal reactor (e.g., the Linde spiral-wound reactor).

4.5.1.3. *Gas Purification*

In further purification, carbon dioxide, residual carbon monoxide, and sulfur compounds (only present in the synthesis gas from partial oxidation) have to be removed as they are not only a useless ballast but above all poisons for the ammonia synthesis catalyst.

The total sulfur contained in the coal and hydrocarbon feedstock is converted in gasification to H_2S and a smaller amount of COS, which are removed as described below. In contrast steam reforming requires removal of sulfur from the natural gas and light hydrocarbon feedstocks upstream of gasification to avoid poisoning of the sensitive reforming catalysts. This is usually performed by hydrodesulfurization and adsorption of the H_2S by ZnO. As this is an essential part of the steam reforming process it is treated in Section Feedstock Pretreatment and Raw Gas Production.

The classical method for CO_2 removal is to scrub the CO_2 containing synthesis gas under pressure with a solvent capable of dissolving carbon dioxide in sufficient quantity and at sufficient rate, usually in countercurrent in a column equipped with trays or packings. The CO_2-laden solvent is flashed, often in steps, to around atmospheric pressure, and the spent scrubbing liquid is subsequently heated and regenerated in a stripping column before being recycled to the pressurized absorption column. In the early days of ammonia production water, often river water, served as solvent in a once-through process without regeneration and recycling.

Today a variety of solvents are used and they can be categorized as physical or chemical solvents. In the physical solvents the carbon dioxide dissolves without forming a chemical compound, and this allows recovery simply by flashing. In the chemical solvents the carbon dioxide becomes fixed as a chemical compound, which needs heat for its decomposition. At low carbon dioxide partial pressures, the chemical solvents absorb substantially more carbon dioxide than the physical solvents; at higher partial pressures the physical solvents (according to Henry's Law, the loading is approximately proportional to the CO_2 partial pressure) have a higher loading capacity than the chemical solvents, for which the solubility approaches a saturation value. Figure 31 shows the loading characteristic for various solvents.

Figure 31. CO_2 loading characteristics of various solvents

As both sour gases, CO_2 and H_2S, have good solubility in the applied solvents, special process configurations are required for partial oxidation gases to recover separately a pure CO_2 fraction and an H_2S-rich fraction suitable for sulfur disposal.

Very suitable for the partial pressure range of CO_2 in steam reforming plants (4 – 7 bar) are chemical solvents based on aqueous solutions of potassium carbonate or alkanolamines containing additional activators to enhance mass transfer and, in some cases, inhibitors to limit or prevent corrosion processes. Primary and secondary amines, for example, monoethanolamine (MEA) and diethanolamine (DEA) exhibit a high mass-transfer rate for carbon dioxide but have a high energy demand for regeneration. For this reason tertiary amines are commonly used today, for example, methyldiethanolamine together with an activator. Triethanolamine does not achieve the required final CO_2 concentration, and in the few cases where it was used it was followed by additional scrubbing with monoethanolamine (MEA).

The potassium carbonate processes from the various licensors differ with respect to the activator, corrosion inhibitor and to some extent in the process configuration.

Over the years considerable progress has been achieved in improving the efficiency of the carbon dioxide removal systems. The first generation of single-train steam reforming ammonia plants used MEA and consumed about 5.8 GJ per tonne NH_3, which was about 14 % of the total energy consumption. Table 23 demonstrates the progress made in energy consumption.

Table 23. Heat requirements for regeneration in CO_2 removal systems [406], [603]

Process	Heat requirement, kJ/mol CO_2
MEA (without Amine Guard)	209
MEA (with Amine Guard III)	116
Benfield hot potash (1-stage)[a]	88
BASF aMDEA process (1-stage)[a]	73
Benfield LoHeat	28 – 35
BASF aMDEA process (2-stage)[b]	28 – 30

[a] Single-stage regeneration.
[b] Two-stage regeneration.

The first progress was made by addition of corrosion inhibitors (e.g., Amine Guard introduced by Union Carbide) [603], [634-637], which allow a higher loading of the solvent. The energy consumption of the modern systems, as shown in the last two lines of Table 23 depends largely on process configuration and required final purity which may range from 50 to 1000 ppm in the purified gas. There is also a trade-off between energy consumption and investment costs.

The hot potash systems, for example, the Benfield process licensed by UOP, differ in the type of activator used to increase the reaction rate between the CO_2 and the solvent. The activators enhance mass transfer and thus influence not only the regeneration energy demand (circulation rate of the solvent) but also the equipment dimensions. The following activators are used: in Benfield [567-570] and Carsol [571], [572] process ethanolamines; in the Giammarco Vetrocoke process glycine (originally arsenic oxide) [575-578]; in the Catacarb system [565], [566] amine borate; in the Exxon Flexsorb HP process [573], [574] a sterically hindered amine; in the Carbosolvan process [580], [584] sulfosolvan B. New activators named ACT-1 (UOP) [585], [586] and LRS-10 [587], [588] (British Gas) have been introduced. All hot potash systems need corrosion inhibitors the concentration of which must carefully to be monitored.

A typical example of an efficient modern hot potash system is the Benfield LoHeat [589] system of UOP. The high thermal efficiency of this two-stage adsorption process using lean and semi-lean solvent is achieved by recompression of the flash steam with an injector or a mechanical vapor compressor. UOP has also developed a number of other process configurations [573], [584], [590], [591], [1280].

BASF's aMDEA [592-594], [595-598] process uses an aqueous solution of the tertiary amine methyldiethanolamine (MDEA) with a special amine activator. No corrosion inhibitors are necessary, and unlike MEA no solvent degradation is observed, so recovery installations are not required. Owing to the low vapor pressure of MDEA and the activator, there are no losses of the active solvent components. The carbon dioxide binds much less strongly to MDEA than to MEA, and the solvent character is more like a hybrid between a strong chemical and a purely physical solvent. On account of the relative weak binding forces, a substantial amount of carbon dioxide can be recovered simply by flashing to low pressure, and only a small amount has to be recovered by stripping. The process is very versatile: increasing the activator concentration shifts the character of the solvent more to the chemical side and vice versa, and process configurations include two- and single-stage designs, the latter allowing old MEA units to be revamped [599-601] simply by swapping the solvent without changing the process equipment.

Physical solvent based processes can also be applied in steam reforming ammonia plants. The Selexol process (UOP) [565], [605-613] uses polyethylene glycol dimethyl ether, the Sepasolv MPE process (BASF) [565], [593]polyethylene glycol methyl isopropyl ether, and the Fluor Solvent Process [614-617] polypropylene carbonate. These solvents are stable, noncorrosive, nontoxic, and not very volatile, but they have a rather high capacity for adsorbing water. For this reason the raw gas has to be dry, which is usually achieved by chilling and operating at low temperatures. The Selexol Process for example operates at 5 °C. The carbon dioxide is recovered simply by flashing; no heat is necessary. Before the solvent is recycled it has to be vacuum treated and/or air stripped to remove traces of carbon dioxide. When comparing the energy consumption of physical and chemical solvent based processes for a given application not only the heat for solvent regeneration but also the mechanical energy for solvent circulation has to be taken into account.

Raw synthesis gas produced by partial oxidation has a carbon dioxide partial pressure between 10 and 30 bar, depending mainly on feedstock and gasification pressure. In the lower half of this partial pressure range chemical solvents based on tertiary amines (e.g., MDEA) might be suitable, but at higher values physical solvents become increasingly preferable. Examples of physical solvent processes are Selexol Process, Sepasolv MPE process, Lurgi Purisol Process (*N*-methylpyrrolidone) [581-583], Sulfinol process (tetrahydrothiophene-1,1-dioxide + diisopropanol) [579], [604], and, probably the most important in this connection, the Rectisol process (Linde and Lurgi) [565], [618-622], [1396], with methanol as solvent operating at –15 to – 40 °C.

The presence of sulfur compounds, mainly H_2S along with a minor quantity of COS, introduces some complications for CO_2 removal from partial oxidation gases. Since the sour gases are both soluble in the solvents and a separate recovery in the regeneration stage is only partially possible (only pure CO_2 can be obtained along with a CO_2 fraction more or less rich in H_2S) two principal plant flowsheets are possible. In one, a first scrubbing stage, which removes the sulfur compounds, is positioned upstream of the shift conversion. The second stage, removing pure CO_2, is located downstream of the shift reactors. This concept reduces the effort required to receive a highly concentrated H_2S fraction suitable for further processing in a Claus plant or a sulfuric acid plant. In the other arrangement, the sour gases are removed after shift conversion, which in this case has to operate over dirty shift catalyst (see Section Carbon Monoxide Shift Conversion) with the consequence that the H_2S is diluted by a large amount of CO_2. In this case, too, methanol regeneration in the Rectisol process can be tailored to achieve a H_2S-rich fraction for downstream processing and pure CO_2, a task difficult to fulfil with the other physical solvents mentioned.

Extensive surveys and additional literature of the CO_2 removal processes are found in [564], [602], [603], [623], [624-627], [628-633], [1332], [1333], [1396] a theoretical analysis is given in [562].

Final Purification. After bulk removal of the carbon oxides has been accomplished by shift reaction and CO_2 removal, the typical synthesis gas still contains 0.2 – 0.5 vol % CO and 0.005 – 0.2 vol % CO_2. These compounds and any water present have to be removed down to a very low ppm level, as all oxygen-containing substances are poisons for the ammonia synthesis catalyst [640].

Methanation. Methanation is the simplest method to reduce the concentrations of the carbon oxides well below 10 ppm and is widely used in steam reforming plants. It is actually the reverse reaction of steam reforming of methane:

$$CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O \quad \Delta H = -206\,\mathrm{kJ/mol} \tag{16}$$

and

$$CO_2 + 4\,H_2 \rightleftharpoons CH_4 + 2\,H_2O \quad \Delta H = -165\,\mathrm{kJ/mol} \tag{17}$$

The advantages of simplicity and low cost more than outweigh the disadvantages of hydrogen consumption and production of additional inerts in the make-up gas to the synthesis loop.

The reaction is carried out over a supported nickel catalyst at a pressure of 25 – 35 bar and a temperature of 250 – 350 °C. The required catalyst volume is relatively small. If a breakthrough of carbon monoxide from the low-temperature shift or carbon dioxide from the absorption system occurs, the intensely exothermic methanation reaction can reach temperatures exceeding 500 °C very quickly [641]. For example, 1 % CO_2 breakthrough leads to an adiabatic temperature rise of 60 °C. Controls should be installed and other security measures taken to avoid these high temperatures because the catalyst may be damaged or the maximum allowable operating temperature of the pressure vessel wall exceeded.

Methanation as final purification for the raw gas from partial oxidation was proposed by Topsøe [642]. In this case the shift conversion is carried out in two stages with a special sulfur-tolerant shift catalyst followed by removal of hydrogen sulfide and carbon dioxide in an acid gas removal unit. Because of the potential danger of a sulfur break-through causing poisoning, the normal copper – zinc – alumina catalyst is usually not applied, which is surprising as the same risk exists in partial oxidation based methanol plants for the similarly composed methanol catalyst.

Selectoxo Process. The Selectoxo process (Engelhard) reduces the hydrogen consumption of the methanation system, as well as the inert gas content of the purified synthesis gas fed to the synthesis loop. After low-temperature shift conversion, the cooled raw gas is mixed with the stoichiometric quantity of air or oxygen needed to convert the carbon monoxide to carbon dioxide. The mixture is then passed through a precious-metal catalyst at 40 – 135 °C to accomplish this selective oxidation [643-646]. The carbon dioxide formed by the Selectoxo reaction adds only slightly to the load on the downstream carbon dioxide absorption system.

Methanolation [647], [648] has been proposed for partially replacing methanation. It converts the residual carbon oxides to methanol, preferably at higher pressure in an intermediate stage of synthesis gas compression. Methanol is removed from the gas by water scrubbing. The methanol may be recycled to the steam reformer feed or recovered as product. As full conversion of the carbon oxides is not achieved, a clean up methanation unit must follow the methanolation section.

Dryers. It is energetically advantageous to add the purified synthesis gas at a point in the synthesis loop where it can flow directly to the synthesis converter (see Section Synthesis Loop Configurations). For this reason water and traces of carbon dioxide must be removed from the make-up gas downstream of methanation. This is accomplished by passing the make-up gas through molecular sieve adsorbers.

Cryogenic methods are usually used for final purification of partial oxidation gases, but may be also incorporated in steam reforming plants. A prominent example is the Braun Purifier process [457], [649-655].

The purifier is a cryogenic unit placed downstream of the methanator and its duty is to remove the nitrogen surplus introduced by the excess of air used in the secondary reformer of the Braun ammonia process (Processes with Reduced Primary Reformer Firing). Additionally the inert level in the synthesis loop is reduced through this unit because methane is completely and argon is partially removed from the make-up gas. Another advantage of the process is that it separates the front-end and the synthesis loop, permitting the H/N ratio in the synthesis loop to be set independent of the secondary reformer. The purifier is a relatively simple unit composed of feed/effluent exchanger, a rectifier column with an integrated condenser and turbo-expander. At –185 °C methane and argon are washed out. The cooling energy is supplied by expansion of the raw gas over the turbo-expander (pressure loss about 2 bar) and expanding the removed waste gas to the pressure level of the reformer fuel.

Liquid Nitrogen Wash [656-658]. Normally, for the partial oxidation processes, only a high-temperature shift conversion is used. This results in a carbon monoxide content of the gas after shift conversion in the range 3 – 5 vol %. Copper liquor scrubbing for carbon monoxide removal, commonly employed in early plants, has become obsolete and is now operated in only a few installations. Not only does it have a high energy demand, but it is also environmentally undesirable because of copper-containing wastewater. Liquid nitrogen wash delivers a gas to the synthesis loop that is free of all impurities, including inert gases and is also the means for adding some or all of the nitrogen required for synthesis.

The nitrogen is liquefied in a refrigeration cycle by compression, cooling, and expansion. It flows to the top of a wash column, where it countercurrently contacts precooled synthesis gas from which most of the methane and hydrocarbons have been condensed. All of the cold equipment is installed in an insulated "cold box." The wash column temperature is about –190 °C. Liquid nitrogen wash systems are in operation at pressures up to 8 MPa corresponding to the highest gasification pressures. Careful surveillance of the inlet gases is required. Water and carbon dioxide in the inlet gas will freeze, causing operating difficulties. Traces of nitric oxide (NO) may react with olefinic hydrocarbons, causing explosions [659], [660].

Normally, an air separation plant is installed in conjunction with liquid nitrogen wash for economy in operation. In modern plants, the air separation and the nitrogen wash frequently are closely integrated with one another so that economies can be realized in the refrigeration system.

Pressure Swing Adsorption. This process can be used to replace the LT shift conversion, carbon dioxide removal, methanation, and even the secondary reformer as well [406], [627], [661-664]. It uses molecular sieves as adsorbents in a series of vessels operated in a staggered cyclic mode changing between an adsorption phase and various stages of regeneration. The regeneration of the loaded adsorbent is achieved by stepwise depressurization and by using the gas from this operation to flush other adsorbers at a different pressure level in the regeneration cycle. The hydrogen recovery may be as high as 90 % depending on the number of adsorbers in one line, which may be as high as 10. Very high purity can be obtained, with about 50 ppm argon and less than 10 ppm of other impurities.

The process scheme for the ammonia plant may consist of production of pure hydrogen followed by separate addition of pure nitrogen from an air separation unit [665-667]. In a special version the nitrogen can be added in the PSA unit itself to increase hydrogen recovery [668-671]. In some processes it may also remove the excess nitrogen introduced with the process air fed to the secondary reformer, e.g. the LCA Process of ICI (ICI LCA Process.). Since this technology has proven its reliability in rather large hydrogen plants for refineries it is now also used for world-scale ammonia plants , e.g., the Linde LAC process (Linde LAC Process.).

4.5.2. *Compression*

Up to the mid-1960s reciprocating compressors were used to compress the synthesis gas to the level of the synthesis loop, which was around 300 bar in the majority of the plants at that time. Higher pressures were used in a few installations, for example, in Claude and Casale units. Prior to about 1950 gas generation processes and shift conversion operated at essentially atmospheric pressure. The gas was first compressed to the level of the CO_2 removal section (usually 25 bar) and afterwards to around 300 bar for final purification (at that time usually copper liquor scrubbing) and synthesis. Reciprocating compressors with as many as seven stages in linear arrangement with intermediate cooling were used, whereby the CO_2 removal section was usually installed between the 3rd and 4th stages. Machines with a suction volume up to 15 000 m^3 (STP) for the first stage were not uncommon. Huge flywheels were designed as the rotors of synchronous motors (ca. 125 rpm) with two crankshafts on both sides connected over crossheads with the piston rod for the horizontally arranged stages. In some instances gas engines were used as drivers.

The rapid technical progress in the hydrocarbon based technologies of steam reforming and partial oxidation made it possible to generate the synthesis gas at a pressure level sufficient for the CO_2 removal operation. As gasification proceeds with a considerable volume increase and feedstocks such as natural gas are usually already available under pressure at battery limits, considerable savings in compression energy are achieved in this way.

Along with the introduction of pressure gasification, horizontally balanced compressors in which the cylinders are in parallel configuration on both sides of a common crankshaft became the preferred design. In these machines a good dynamic balance can readily be achieved, higher speeds are possible and also the use of asynchronous motors is possible. The low height of the arrangement has less severe requirements for foundations, allows simpler piping connections and facilitates maintenance. When gas engine drivers (two-stroke type) were used instead of electric motors, some designs applied a common crankshaft for the piston rods of the gas machine cylinders and compressor cylinders. In a very few cases steam turbines with special speed reduction gears have been used. In smaller plants, the various compression services, e.g., natural gas, process air, and synthesis gas compression, were apportioned among the crankshaft throws in such a manner that a single compressor can perform all compression duties [672]. Further information on reciprocating compressors is given in [673], [674], [677], [678].

One of the most important features of the energy integrated single-stream steam reforming ammonia plant pioneered by M. W. Kellogg in 1963 was the use of centrifugal compressors for the compression duties of synthesis gas and recycle, process air, and refrigeration. From this time onwards application of centrifugal compressors became standard practice in most ammonia plants irrespective of the synthesis gas generation technology. The fundamental advantage of these machines are low investment (single machines even for very large capacities) and maintenance cost, less frequent shutdowns for preventive maintenance, and high reliability (low failure rate) [958]. In most cases the centrifugal compressors in ammonia plants are directly driven by steam turbines. This avoids the losses associated with generation and transmission of electric power. For this reason the overall efficiency of a plant with steam-driven centrifugal compressors is superior, although the centrifugal compressors are inherently less efficient than reciprocating units. A further advantage is that centrifugal compressors require only a fraction of the space needed for reciprocating compressors.

Manufacturing capabilities limit the minimum possible passage width (today about 2.8 mm) at the outer circumference of a centrifugal compressor impeller and this imposes a limit on the minimum effective gas volume leaving the last impeller. Unless the total volumetric gas flow has a reasonable relationship to the passage width of the last impeller and the pressure ratio, excessive pressure losses would occur within the passage and in the diffusers between the impellers, rendering the machine extremely ineffective. The first single-train ammonia plants with a capacity of 550 – 600 t/d had to lower the synthesis pressure to 145 – 150 bar to meet the required minimum gas flow condition. Today, with improved manufacturing techniques, the minimum gas flow from the last wheel is 350 m^3 for synthesis gas with a molecular mass of about 9 and an efficiency of around 75 %. This corresponds to a capacity of 400 t/d at 145 bar. As newer synthesis catalysts allow a pressure of 80 bar in the synthesis loop (ICI's LCA Process, Kellogg's KAAP) a centrifugal compressor could be used down to 220 t/d. Of course, for today's world-scale capacities of 1200 – 2000 t/d these technical limitations have no influence on the synthesis pressure, which even for plants with 1800 t/d is between 155 and 190 bar [404], [406], [675], [676], [679].

The tensile strength of the steels normally used to manufacture the compressor impellers allow a maximum wheel tip speed of about 330 m/s, which limits the pressure increase attainable by each impeller. A pressure increase, for example, from 25 to 200 bar would require 18 – 20 impellers. However, a compressor shaft must have sufficient rigidity to avoid excessive vibration, and this limits the possible length such that a compressor shaft cannot accommodate more than eight or nine impellers. It is therefore necessary to arrange several compressor casings in series, with compression ratios from 1.8 to 3.2.

To overcome the pressure drop (5 – 20 bar) in the synthesis loop re-compression of the recycle gas is required. In practically all modern ammonia plants, the shaft of the final casing also bears the impeller for the compression of the recycle gas. Depending on synthesis configuration, mixing of make-up gas and recycle can be performed inside the casing or outside (three or four-nozzle arrangement; Fig. 34).

In older plants which used a reciprocating compressor for the recycle, a recycle cylinder was often mounted together with the other cylinders on the reciprocating frame. Sometimes special rotary compressors, so-called mole pumps were also used, with the unique feature that compressor and electric driver were completely enclosed in a common high-pressure shell. In old Casale plants, the make-up gas was introduced into the high pressure recycle loop and acted as the driving fluid of an injector which compressed the recycle gas.

Today modern plant concepts for world-scale capacity plants tend to limit the number of compressor casings to two. Figure 32 shows an example of the synthesis gas compressor of a large ammonia plant.

Figure 32. Centrifugal compressor for make-up and recycle gas compression of an ammonia plant (courtesy of Uhde)

a) Air cooler; b) Separator; c) Silencer; d) Water cooler

Geared or metal diaphragm couplings are used to connect the shafts of the individual casings (two in Figure 32). These flexible couplings prevent possible compressor damage resulting from slight misalignment and shaft displacement.

Sealing of the rotating shaft against the atmosphere is an important and demanding task. The high pressures and the high rotational speeds involved do not allow mechanical contact shaft seals. Usually, liquid-film shaft seals with cylindrical bushings (floating rings) are applied [680]. In this concept, an oil film between the shaft and a floating ring, capable of rotation, provides the actual sealing. The floating ring is usually sealed to the compressor casing by O-rings. Seal oil flows between both halves of the floating ring. Part of the oil returns to the reservoir, while the remainder flows against the gas pressure into a small chamber from which, together with a small quantity of gas, it is withdrawn through a reduction valve. Figure 33 is a schematic diagram of a liquid film shaft seal.

Figure 33. Liquid film shaft seal with cylindrical bushing for a high-pressure centrifugal compressor

a) Shaft; b) Bearing; c) Pressure side; d) Ambient side; e) Floating seal rings; f) Seal oil surge vessel; g) Seal oil; h) Lube oil; i) Drain to gas – oil separator; k) Drain to lube oil tank; l) Elevation for seal oil head

The seal oil pressure in the floating ring cavity must always be slightly higher than the gas pressure within the casing which is provided by static height difference of the oil level in the elevated oil buffer vessel. In this way normally no oil should enter into the synthesis gas. As the labyrinth section on the pressure side is connected with the suction side through an equalizing line, it is necessary to seal the compressor shaft towards the atmosphere only at suction pressure level.

Often, seal oil supply is combined with the lubricating oil system, with oil reservoir, filters and (in part) pumps in common.

The high rotational speeds and the relatively large masses of the compressor rotors place high demands on the performance of the bearings. This is especially true for the thrust bearings, which must withstand high thrust forces. The minimum clearances necessary at the labyrinths and the impellers allow practically zero wear. Any wear resulting in friction could lead instantly to severe damage. For these reasons, in addition to measuring bearing temperatures, the axial position of the rotor and the radial vibrational deflections are continuously monitored by sensors. An increased vibrational amplitude is often an early indication of mechanical faults, such as rotor imbalance, bearing damage, occurrence of friction, or misalignment.

An interesting concept is dry (oil-less) gas seals for centrifugal compressors. Development dates back to 1969 and the first commercial application was in a natural-gas compressor in 1973. Since then they have been widely used in off-shore service [681-683]. Only recently have they gained acceptance in the ammonia industry, where several compressors for synthesis gas and refrigeration duty equipped with dry seals have been successfully placed in service. Nitrogen is used as an inert fluid for the seal, which is achieved at the radial interface of rotating and stationary rings. During operation the seal is not completely tight; some of the seal gas flows back to the suction side to be re-compressed, and a small amount from the suction side may go to the atmospheric side and is sent to the flare on account of its content of combustibles. During stops, when the shaft is not rotating, the seal ring is pressed tight against the seat by means of a spring and the differential gas pressure. Dry gas seals in combination with oil-lubricated bearings (dry/wet) have the advantage that a much smaller oil system is required and that there is no contact between oil and gas, which eliminates an emission source.

A new development, already in commercial service, but so far not used in ammonia plants, is magnetic bearings [681], [684]. Magnetic bearings promise a wider temperature range, are less prone to wear, are less prone to developing vibrations due to imbalance and require less maintenance. A combination of magnetic bearings and dry seals (dry/dry) could totally eliminate the oil system.

Integrated geared centrifugal compressors developed by DEMAG and GHH are a new development which might become of interest for plants of smaller capacity operating at lower pressure. The driver (e.g., a steam turbine) drives a common gear to which the individual compression stages are connected. Each stage has a single impeller which runs with very high speed, for example, 25 000 rpm or higher. Compressors with three or four stages are in operation, for example, a methanol synthesis compressor for 75 000 m^3/h and a pressure of 75 bar. It is likely that this concept can be extended to a final pressure of 120 bar with ammonia synthesis gas.

Compressor control is achieved basically by controlling the rotational speed of the driver, in modern plants often with the help of a distributed control system (DCS). If the volumetric flows through the machine at start-up or during reduced load operation deviate too far from the design values, it is necessary to re-circulate gas through individual stages or through the whole machine. Otherwise the compressor can enter a state of pulsating flow, called surge, which could cause damage. Anti-surge control (minimum by-pass control, kickback control) is designed to prevent this condition, as well as to minimize the incidence and degree of uneconomical re-circulation. A point of discussion is sometimes the minimum load at which the compressor can run without kickback, which means without loss of efficiency. Usually a load of 75 % is possible, and with special impeller design, the value may be lowered to 70 % but with a slight sacrifice of full-load efficiency.

Other compression duties in the plants, such as process air in steam reforming plants and air, and oxygen, and nitrogen compression in partial oxidation plants, are also performed by centrifugal compressors. Also for the ammonia compression in the refrigeration section centrifugal compressors are normally in service. In some cases screw compressors have been used for this duty on account of their good efficiency and load flexibility, which is of interest in plants where the ammonia product is split between direct users at the site and cold storage in changing ratios.

Criteria for compressor selection and economic comparisons are discussed in [685-692, 704]. Additional information is given in [693-703].

In modern plants the synthesis gas compressors, including recycle, are almost exclusively driven by a steam turbines. These are generally extraction turbines with a condensing section. Steam is extracted at suitable pressure levels (e.g. 45 – 55 bar) to provide, for example, the process steam in steam reforming plants, and for other drivers, e.g., air compressor, ammonia compressor, boiler feed water pumps, and blowers.

As failures and breakdowns of these large rotary machines could lead to long and expensive repairs and to a corresponding loss of production it is advisable to keep the essential spare parts, for example, spare rotors, in stock. In older steam turbines, sometimes blade failures occurred, but this is no longer a problem due to improved blade design and shroud bands, which are standard today.

Gas turbines have also been used as drivers for compressors in ammonia plants. The exhaust may be used for steam production, for preheating duties, or as combustion air in the primary reformer [705-709].

4.5.3. *Ammonia Synthesis*

Under the conditions practical for an industrial process ammonia formation from hydrogen and nitrogen

$$N_2 + 3\,H_2 \rightleftharpoons 2\,NH_3 \quad \Delta H = -92.44\ \mathrm{kJ/mol}$$

is limited by the unfavorable position of the thermodynamic equilibrium, so that only partial conversion of the synthesis gas (25 – 35 %) can be attained on its passage through the catalyst. Ammonia is separated from the unreacted gas by condensation, which requires relatively low temperatures for reasonable efficiency. The unconverted gas is supplemented with fresh synthesis gas and recycled to the converter. The concentration of the inert gases (methane and argon) in the synthesis loop is controlled by withdrawing a small continuous purge gas stream. These basic features together with the properties of the synthesis catalyst and mechanical restrictions govern the design of the ammonia synthesis converter and the layout of the synthesis loop. Evaluation criteria are energy consumption, investment and reliability.

4.5.3.1. *Synthesis Loop Configurations*

A number of different configurations are possible for the synthesis loop. They can be classified according to the location of ammonia condensation and the point at which the make-up gas is introduced. Figure 34 shows the principal possibilities.

If the make-up gas is absolutely free of catalyst poisons, such as water and carbon dioxide (for example, after molecular sieve dehydration or liquid nitrogen wash), it can be fed directly to the synthesis converter (Fig. 34 A). After the gas leaves the synthesis converter, ammonia is condensed by cooling and the recycle gas is referred to the recycle compressor. This represents the most favorable arrangement from a minimum energy point of view. It results in the lowest ammonia content at the entrance to the converter and the highest ammonia concentration for condensation.

Figure 34. Schematic flow diagrams of typical ammonia synthesis loops

A) Synthesis loop for pure and dry make-up gas; B) Product recovery after recycle compression; C) Product recovery before recycle compression (four-nozzle compressor design); D) Two stages of product condensation

a) Ammonia converter with heat exchangers; b) Ammonia recovery by chilling and condensation; c) Ammonia recovery by condensation at ambient temperature; d) Synthesis gas compressor; e) Recycle compressor

When the make-up gas contains water or carbon dioxide, advantage is taken of the fact that these materials are absorbed completely by condensing ammonia. This requires that the condensation stage be located partially or wholly between the make-up gas supply point and the converter. This arrangement has the disadvantage that the ammonia concentration for condensation is reduced by dilution with the make-up gas. Also, at equal condensing temperature, a higher ammonia concentration exists at the inlet to the converter. Figure 34 B shows the simplest such configuration. An additional drawback of this arrangement is that all the ammonia produced must be compressed with the recycle gas in the recycle compressor.

The scheme shown in Figure 34 C, the frequently used “four-nozzle compressor”, avoids this waste of energy. With this arrangement, recycle compression follows directly after condensing and separating the ammonia. In this configuration, it is possible to cool the recycle gas using cooling water or air immediately before admixing the make-up gas (i.e., before diluting the recycle gas) and thereby to reduce the energy expenditure for refrigerated cooling.

Splitting the cooling step for ammonia condensation also offers advantages when the recycle gas is compressed together with the make-up gas. This applies especially at synthesis pressures above about 25 MPa (250 bar). At these pressures, a greater portion of the ammonia formed can be liquefied by cooling with cooling water or air (see Fig. 34D).

When ammonia-containing recycle gas and carbon dioxide containing make-up gas mix together under certain conditions of concentration and temperature, precipitation of solid ammonium carbamate can result.

In recent years, also as a retrofit in existing plants, molecular sieve drying of make-up gas has increasingly been applied in order to realize the energy-saving arrangement of the synthesis loop corresponding to Figure 34 A.

4.5.3.2. *Formation of Ammonia in the Converter*

The central part of the synthesis system is the converter, in which the conversion of synthesis gas to ammonia takes place. Converter performance is determined by the reaction rate, which depends on the operating variables (cf. Section Kinetics). The effect of these parameters is discussed briefly in the following.

With increasing pressure, ammonia formation increases (Fig. 35). This results not only from the more favorable equilibrium situation for the reaction, but also from the effect on the reaction rate itself. In industrial practice, there are plants that operate at about 8 MPa (80 bar), but there are also those that operate at more than 40 MPa (400 bar). Today, plants are built mainly for synthesis pressures of 150 – 250 bar. Typical operating parameters for modern synthesis loops with different pressures are listed in Table 24.

Table 24. Typical operating parameters for modern synthesis loops at 140 and 220 bar (1000 t/d NH_3) [404, p. 226]

Parameters	Inlet pressure, bar	
	140	220
Inlet flow, Nm^3/h	500 000	407 000
Inlet NH_3 conc., mol %	4.1	3.8
Outlet NH_3 conc., mol %	17.1	19.9
Inlet inert conc., mol %	8.0	12.0
NH_3 separator temperature, °C	–5	–5
Relative catalyst volume	1	0.6

Figure 35. Performance for a four-bed quench converter as a function of operating pressure with space velocity (per hour) as parameter; 10 % inerts in the inlet synthesis gas

Converter performance decreases with increasing inert gas content (Fig. 36). The usual range is 0 – 15 vol %. For a secondary loop based on purge gas, it can be 30 % or more (see Section Inert-Gas and Purge-Gas Management).

Figure 36. Performance of a converter as a function of inlet inert gas (CH_4 and Ar) content with space velocity (per hour) as parameter, inlet NH_3 content is 3.5 %; 30 MPa pressure; catalyst particle size is 6 – 10 mm

Converter performance also diminishes (Fig. 37) with increasing oxygen content of the synthesis gas. Today, a level of 10 ppm in the make-up gas, corresponding to about 3 ppm in the converter inlet gas, is usually, not exceeded (cf. Section Catalyst Poisons).

Figure 37. Performance of a converter as a function of oxygen content (all oxygen-containing impurities) in the inlet synthesis gas

In contrast to the above-mentioned variables, the dependence of the converter performance on the H_2/N_2 ratio shows a true maximum (Fig. 38). The optimum conversion at high space velocity [SV = m^3 (STP) gas $h^{-1} \cdot m^{-3}$ catalyst] lies close to an H_2/N_2 ratio of 2 and approaches 3 at low space velocities. The reason is that equilibrium plays a greater role at low space velocities and has a maximum at a ratio of 3, except for small corrections [14] with regard to the behavior of real gases. Usually, the ratio is adjusted to 3, because in most plants, conversions near equilibrium are attained.

Figure 38. Ammonia conversion as a function of hydrogen/nitrogen ratios in the inlet synthesis gas with space velocity (per hour) as parameter; 9.7 MPa pressure [1136]

In practice, space velocities vary from about 12 000 h^{-1} at about 15 MPa (150 bar) to about 35 000 h^{-1} at about 80 MPa (800 bar). Usually, with increasing space

velocity, the ammonia concentration in the effluent synthesis gas from a given converter does indeed go down (Figs. 35, 36, 38). However, the operating point normally chosen means that the increase in gas flow rate more than compensates for the reduced ammonia concentration. Thus, a still higher ammonia production rate is achieved. Plant operation often takes advantage of these phenomena. For example, this characteristic can be used to maintain ammonia production rate when the synthesis catalyst ages and its activity declines. Increasing converter flow rate and declining synthesis catalyst activity can reach a point, even with careful control, where the reaction "blows out" and production ceases. This occurs when the heat of reaction is no longer sufficient to provide the temperatures necessary for operation of the feed – effluent heat exchanger. The heat exchanger then fails to heat the cold converter feed gas to the required reaction "ignition" temperature. Achieving maximum ammonia production requires operating in the neighborhood of this "blow out" point, in turn requiring very careful control [710-712]. If the synthesis converter is to be operated in this region, then it is advisable to oversize the converter feed – effluent heat exchanger system to attain a higher degree of control stability.

Converter Design. Design of ammonia synthesis reactors is not just the calculation of the required catalyst volume; other parameters have to be considered, too, and for some of them optimum values have to be found. This raises the question of the definition of optimum. In the early days with more strict material and fabrication-related limitations the converters were usually designed for minimum high-pressure volume, and this meant maximum use of the catalyst. Today the objective is to optimize the heat recovery (at the highest possible level) and to minimize the investment for the total synthesis loop.

The design of an ammonia converter is a demanding engineering and chemical engineering task. To calculate the parameters for the design, including dimensions and number of catalyst beds, temperature profiles, gas compositions, and pressure drop, a suitable mathematical model is required.

Two differential equations describe mathematically the steady-state behavior of the reactor section of a converter. The first models the concentration – position relationship for transformation of the reactants to products, i.e., the reaction kinetic equation (cf. Section Kinetics). The second handles the temperature – position behavior of the reacting synthesis gas, the catalyst, and the vessel internals. The form of the latter is characteristic of the type of converter. The temperature profile depends not only on the rate of reaction heat evolution but also on the method and nature of the system for removing heat from the catalyst bed or beds. Additional equations describe the behavior of the separate feed – effluent heat exchanger system [713-717]. General information on converter calculations are given in [127], [716-718]. Computer programs and applications can be found in [719-722]. For a discussion of modeling of different converter types, see [713-717], [723], [724]. Models for multibed quench converters are described in [723-730]. Tubular reactors are treated in [732-739]. The individual effects of the operational parameters are evaluated in [14], [130], [731].

The reaction temperature profile is of particular importance because the reaction rate responds vigorously to temperature changes. Figure 39 plots lines of constant reaction rate illustrating its dependence on temperature and ammonia concentration in the reacting synthesis gas. The line for zero reaction rate corresponds to the temperature – concentration dependence of the chemical equilibrium. From Figure 39 it is apparent that there is a definite temperature at which the rate of reaction reaches a maximum for any given ammonia concentration. Curve (a) represents the temperature – concentration locus of maximum reaction rates. To maintain maximum reaction rate, the temperature must decrease as ammonia concentration increases.

Figure 39. Nitrogen reaction rate v in m^3 NH_3 / (m^3 catalyst · s) as a function of temperature and ammonia concentration at 20 MPa pressure and 11 vol % inerts in the inlet synthesis gas

a) Locus of temperatures resulting in maximum reaction rate at a given ammonia concentration

If the objective in design or operation were optimizing catalyst utilization, then Figure 39 shows that the converter temperature – composition profile should follow curve (a), which corresponds to maximum reaction rate at all points. It is also obvious that in reality this "ideal" temperature – concentration profile cannot be achieved. For example, a synthesis gas with about 3 % ammonia concentration entering the converter cannot be heated to the "ideal" temperature by heat exchange because the very high temperature required does not exist in the converter system. To reach the "ideal" temperature, the first portion of the catalyst must initially operate adiabatically. Consideration of the service life of the catalyst requires that this maximum initial temperature not exceed that recommended by the manufacturer, usually 530 °C (cf. Section Catalyst Reduction). Following this initial adiabatic temperature rise, it is possible to minimize the required catalyst volume by cooling the reacting synthesis gas such that, as ammonia formation progresses, the temperature follows curve (a). In the days when converters were designed to operate at very high pressures and temperatures and before the advent of improved construction materials, the converter design represented a real limitation on plant capacity. To maximize converter output and plant capacity to achieve the most favorable overall manufacturing cost, it was necessary to optimize catalyst utilization. A converter temperature – concentration profile was often compared to the "ideal" for optimum usage of high-pressure vessel and catalyst volumes [731], [740].

Commercial Ammonia Converters.
Principal Reactor Configurations. Commercial converters can be classified into two main groups:

1. Internally cooled with cooling tubes running through the catalyst bed or with catalyst inside the tubes and the cooling medium on the shell side. The cooling medium is mostly the reactor feed gas, which can flow counter- or cocurrently to the gas flow in the synthesis catalyst volume (*tube-cooled converters*).
2. The catalyst volume is divided into several beds in which the reaction proceeds adiabatically. Between the individual catalyst beds heat is removed by injection of colder synthesis gas (*quench converters*) or by indirect cooling with synthesis gas or via boiler feed water heating or raising steam (*indirectly cooled multibed converters*).

The gas flow can have an axial, cross-flow or radial flow pattern. The different cooling methods can be combined in the same converter.

The severe conditions of high pressure, high temperature, and high hydrogen partial pressures place strict requirements on the construction materials and design for both groups. For example, almost all converters consist of an outer pressure vessel containing a separate inner vessel housing the catalyst and other internals, such as gas distributors and heat exchangers. Relatively cool converter feed gas flows through the annular space between the outer pressure shell and the internal "basket". This shields the outer shell from the high-temperature "basket", permitting use of comparatively low-alloy chromium – molybdenum steels for its construction. Often, part of the converter feed – effluent heat-exchange system surface is placed within the converter pressure shell. By this means, the nozzle penetration through the pressure shell for the converter effluent gas is also maintained at relatively low temperature. Today, this latter feature is not always necessary; the state of the art in converter construction materials now allows design of exit nozzles for the maximum anticipated temperatures, i.e., up to about 530 °C. References [745] and [746] review some literature on ammonia converters.

Tube-Cooled Converters. To remove the heat evolved in the synthesis reaction, converters have been designed in which cooling tubes run through the catalyst bed. With these tubes, the heat is transferred to the converter feed gas to heat it to the reaction ignition temperature or to an external cooling medium. The known designs for such converters are suited only for small production capacities and therefore currently of limited interest. When designed to utilize the heat of reaction for heating the converter feed gas, such converters have the further disadvantage that temperature control is sluggish and temperature oscillations dampen out very slowly, if at all, a phenomenon called "hunting".

Typical of such converters is the countercurrent design of the Tennessee Valley Authority (TVA) [710], [737], [740], [749-751], [757-759]. Part of the feed gas to this unit enters the converter at the top and flows down through the annular space between the pressure shell and the basket. The main gas flow enters the converter at the bottom and joins the shell cooling gas. The mixture is heated to about 200 °C in an internal exchanger located beneath the catalyst bed. The gas then enters the cooling tubes that run through the catalyst bed (Fig. 40 A). There it absorbs the heat released in the reaction and reaches the required reaction ignition temperature of about 400 °C. The reaction begins almost adiabatically in the catalyst bed. As the reacting gas temperature rises, the temperature difference between the reacting gas and the cooling tubes increases, resulting in increasing heat removal (Fig. 40 B). As the reacting gas reaches the bottom of the catalyst bed, the rate of reaction begins to decrease sufficiently, because of high ammonia concentration, that cooling predominates and the temperature of the reacting gas begins to fall. Figure 40 C shows the converter temperature – concentration profile. The reaction temperature at first somewhat exceeds that for maximum reaction rate but eventually falls below curve (a). Cold converter feed gas can be admitted at a point within the internal heat exchanger to control both the total system and reaction temperature profiles through bypassing. Casale has employed a similar converter design concept [760].

Figure 40. Countercurrent tube-cooled converter (TVA converter) [740]

B) Gas temperature profile through the converter; C) Ammonia concentration versus temperature (cf. Fig. 39)

Other tube-cooled converters with countercurrent flow are the Mont Cenis reactor [741-744], the original Haber – Bosch reactors [741], the Claude converter [559], [563], and the older Fauser design [559]. These converters were all used in relatively small plants and are now obsolete.

An interesting rebirth of the countercurrent principle is the new ICI tube cooled converter used in the LCA process(Fig. 41) [1404].

Figure 41. ICI tube-cooled ammonia converter

a) Top of catalyst bed; b) Cooling tubes; c) Catalyst;

The Nitrogen Engineering Corporation (NEC) converter applies cocurrent flow by means of bayonet tubes [740], [749], [751-758]. This design places maximum heat-exchange temperature difference — therefore, maximum cooling performance — at the catalyst bed inlet, the point where maximum reaction rate — therefore maximum rate of heat evolution — is taking place. The intent is to obtain closer approach to curve (a) (cf. Fig. 42 C). Figure 42 A shows the general arrangement of the converter, catalyst bed, and heat exchanger; Figure 42 B, the temperature profile of the system. Chemico, a derivative of NEC, continued to apply such converters with only slight changes [760].

Figure 42. Cocurrent-flow tube-cooled converter [740]

B) Gas temperature profile through the converter;

C) Ammonia concentration versus temperature (cf. Fig. 39)

Ammonia Casale developed a new converter concept which uses no tubes but arranged cooling plates. The plates are radially immersed in the axial – radial catalyst bed to remove the reaction heat while it is formed. Figure 43 [1415] shows the temperature profile of this pseudo-isothermal reactor. The profile follows the line of the maximum reaction rate to obtain the highest possible conversion per pass from a given catalyst volume. The use of plates allows a design without tubesheets and simplifies catalyst loading and unloading and the use of small size high active catalyst. The new Casale IAC ammonia converter is suited for very high capacities up to 4500 t/d for the the so-called mega-ammonia plants presently in discussion. The first commercial use of a converter of this type is operating successfully in a 1050 stpd (953 mtpd) plant in Trinidad [1336]. In a recent Casale company brochure the plate arrangement is shown taking a methanol converter as an example (Fig. 44).

Figure 43. Expected thermal profile of catalyst along the converter and comparison with plant data [1415]

Figure 44. Internals of a Casale isothermal converter (courtesy of Ammonia Casale)

Today, the great majority of synthesis converters are designed with catalyst distributed in several beds, within one or more reactor vessels. In each bed, the synthesis gas reacts adiabatically, and direct or indirect cooling is provided between the catalyst beds for cooling the reacting mixture from a temperature above to a value below the “ideal” (curve (a), Fig. 45).

Multibed Reactors with Direct Cooling (Quench Converters). In quench converters cooling is effected by injection of cooler, unconverted synthesis gas (cold shot) between the catalyst beds. The catalyst beds may be separated by grids designed as mixing devices for main gas flow and cold shot, or be just defined by the location of cold gas injection tubes as for example in the ICI lozenge converter.

In this type of converter only a fraction of the recycle gas enters the first catalyst layer at about 400 °C. The catalyst volume of the bed is chosen so that the gas leaves it at ca. 500 °C (catalyst suppliers specify a maximum catalyst temperature of 530 °C). Before it enters the next catalyst bed, the gas is “quenched” by injection of cooler (125 – 200 °C) recycle gas. The same is done in subsequent beds. In this way the reaction profile describes a zig-zag path around the maximum reaction rate line. A schematic drawing of a quench converter together with its temperature/location and temperature/ammonia concentration profiles is presented in Figure 45.

Figure 45. Multibed converter with quench cooling [1137]

A) Converter; a) Catalyst; b) Heat exchanger; c) Quench gas inlets; d) Gas inlet; e) Gas exit

B) Gas temperature profile through the converter;

C) Ammonia concentration versus temperature (cf. Fig. 39)

A disadvantage is that not all of the recycle gas passes over the entire catalyst volume so that considerable ammonia formation occurs at higher ammonia concentration and therefore at lower reaction rate. Therefore a higher catalyst volume is needed compared to an indirectly cooled multibed converter. However, no extra space is required for interbed heat exchangers, so that the total volume of the high-pressure vessel will remain about the same as that for the indirectly cooled variant [775].

As the quench concept was well suited to large capacity converters it had a triumphant success in the early generation of large single-train ammonia plants constructed in the 1960s and 1970s. Mechanical simplicity and very good temperature control contributed to the widespread acceptance. For example, M. W. Kellogg alone has installed more than 100 of its quench converters. Though being increasingly replaced by the indirect-cooling concept by revamp or substitution they are still extensively used. Descriptions of earlier designs of Kellogg, BASF, and Uhde can be found in [746-748], [757].

The most important example is the M. W. Kellogg three- or four-bed converter [746], [776-778] (Figure 46). In this design, the catalyst “basket” is not easily removable from the pressure vessel. The catalyst can be changed by draining it at the bottom of the converter through “downcomers” that connect all catalyst beds with one

another. The converter feed – effluent exchanger, attached to the top head, is designed for disassembly.

Figure 46. Kellogg four-bed vertical quench converter

a) Gas inlet; b) Catalyst bed; c) Basket; d) Quench; e) Interchanger; f) Gas outlet; g) Bypass

Other designs were used by BASF [746], Casale [746], Chemico, Grand Paroisse [745], ICI [746], Uhde [746], and others.

An interesting variant in this group is the ICI lozenge converter [288], [741], [746], [760], [776]. This design (Fig. 47) has a single catalyst bed that is divided into several zones (usually four) by quench gas distributors, through which colder recycle gas is injected evenly across the whole cross section of the catalyst bed. For this reason it is justifiable to classify this converter as a multibed type. The distributors consist of banks of transverse sparge pipes which deliver gas at regular intervals along their length. The spargers are in a void space within horizontal mesh-covered structures, whose cross section is lozenge shaped so that the catalyst particles can flow freely past them during loading and unloading. A special version of this reactor concept is the opposed flow design [779], [780], suggested for very large capacities. In this configuration the converted gas is collected and withdrawn from the middle of the catalyst bed, with down-flow in the upper half and up-flow in the lower half of the catalyst bed. The uninterrupted catalyst bed is maintained in the opposed-flow converter. A design similar to that of ICI with direct injection of the quench gas into the single catalyst bed has been proposed by Chemico [781].

Converters with axial flow face a general problem: with increasing capacity the depth of the catalyst beds must be increased because for technical and economic reasons it is not possible to increase the bed diameter, and thus the pressure vessel diameter, above a certain limit. To compensate for the increasing pressure drop conventional axial flow converters have to use relatively large catalyst particles, which have the disadvantage of lower activity compared to smaller particles mainly on account of diffusion restriction. *Radial gas flow* in the converter avoids this dilemma, and with this concept it is possible to design converters for very large capacities without excessive diameters and with low pressure drop, even with small catalyst particle size. The advantages of radial flow are discussed in [783-786]. Radial flow has been also applied in tube-cooled converters [787]. The first radial flow converter introduced commercially and then widely used was the Topsøe S 100 converter [741], [746], [776], [789-794], which has two catalyst layers with a catalyst particle size of 1.5 – 3 mm. Figure 48 shows a schematic of the converter [404].

The major part of the gas enters the vessel at the top and flows down as shell cooling gas. It then passes through the feed – effluent heat exchanger and flows upwards through a central pipe to the first catalyst bed, which is traversed from the inside to the outside. After the effluent from the first bed has been quenched with cooler recycle gas, it enters the second bed and passes through it in the inward direction. The cold gas enters through the bottom of the vessel and is mixed with the inlet gas to the first bed for temperature control.

Radial flow quench converters have also been used by Chemoproject [796], Österreichische Stickstoffwerke [797], and Lummus [798].

Axial – radial flow pattern was introduced by Ammonia Casale. Converters with strictly radial gas flow require mechanical sealing of the top of each catalyst bed and dead catalyst volume with little or no flow to avoid bypassing of the catalyst. In the Casale concept there is no need for a dead catalyst zone as the annular catalyst bed is left open at the top to permit a portion of the gas to flow axially through the catalyst. The remainder of the gas flows radially through the bulk of the catalyst bed. As shown in Figure 49 this is achieved by leaving the upper part of the catalyst cartridge at outlet side unperforated so that gas entering from the top is forced to undergo partially axial flow.

Figure 49. Ammonia Casale axial – radial flow pattern

a) Unperforated wall; b) Perforated wall

Crossflow was chosen as a different approach by M. W. Kellogg in their horizontal quench converter to obtain low pressure drop even with small catalyst particles [745], [770], [790], [791], [800], [801, 1271]. The catalyst beds are arranged side by side in a removable cartridge which can be removed for catalyst loading and unloading through a full-bore closure of the horizontal pressure shell. As the cartridge is equipped with wheels it can be moved in and out on tracks, thus needing no crane. The gas flows vertically from the top to the bottom. The temperature difference between the top and the bottom requires special design measures to prevent uneven circumferential warming of the pressure shell and to avoid bending.

Multibed Converters with Indirect Cooling. In converters of this type cooling between the individual beds is effected by indirect heat exchange with a cooling medium, which may be cooler synthesis gas and/or boiler feed water heating and steam raising. The heat exchanger may be installed together with the catalyst beds inside one pressure shell, but an attractive alternative, especially for large capacities, is to accommodate the individual catalyst beds in separate vessels and use separate heat exchangers. This approach is especially suitable when using the reaction heat for raising high-pressure steam. The indirect cooling principle is applied today in most large new ammonia plants, and also in revamps an increasing number of quench converters are modified to the indirect cooling mode. Figure 50 shows a schematic of the principle together with temperature/location and temperature/ammonia concentration profile.

B) Gas temperature profile through the converter;

C) Ammonia concentration versus temperature (cf. Fig. 39)

Converters with indirect cooling have been known since the early days of ammonia production, for example, the Fauser – Montecatini reactor [741], [745], [746], [757], [803-805]. In this converter, tube coils between catalyst beds transfer the reaction heat to a closed hot water cycle under pressure, operating by natural draft. The hot water releases the absorbed heat in an external steam boiler generating about 0.8 t of steam per tonne of ammonia at about 45 bar (ca. 250 °C).

In the well-known Uhde – Chemie Linz converter with three catalyst beds — described in various versions [731], [745], [746], [761-764], [776] — the indirect cooling is provided by converter feed gas. Feed gas enters at the top, passes down the annulus between basket and shell to cool the pressure wall, flows through the shell side of the lower feed – effluent heat exchanger, and then via the center pipe and interbed exchangers to the top of the first catalyst bed. The gas passes downwards through the catalyst beds and the tube side of the interbed exchangers and the lower heat exchanger to leave the reactor vessel. For trimming purposes a quench is foreseen.

Further development of the radial flow concept used in the quench converter Topsøe Series 100 has led to the successful launch of the Topsøe Series 200 converter [552], [765], [766], [783], [807-811], designed for indirect cooling. Two versions are shown in Figure 51, with and without a lower internal heat exchanger. A “cold shot” ahead of the first catalyst bed is installed for temperature adjustment.

Figure 51. Topsøe Series 200 converter

a) Pressure shell; b) Interbed heat exchanger; c) 1st Catalyst bed; d) Annulus around catalyst bed; e) 2nd Catalyst bed; f) Lower heat exchanger; g) Cold bypass; h) Cold bypass pipe

In the converter without a lower exchanger the feed gas enters at the bottom and flows as pressure wall cooling gas to the top of the converter. After passing the centrally installed interbed exchanger on the tube side, the gas is mixed with cold gas for temperature adjustment and passes through the first catalyst bed radially from the outside to the inside. The exit gas flows through the shell side of the interbed exchanger before it enters the second bed, which is crossed in the same direction as the first one. The Topsøe Series 300 converter contains three catalyst beds and two central interbed exchangers in a single pressure shell.

Casale [813-818] has also successfully commercialized converters based on the axial – radial flow concept with indirect cooling.

Kellogg has re-engineered its horizontal cross-flow quench converter for indirect cooling [745], [770], [771], [827], [828]. (Fig. 52) As in the quench version the pressure shell has a full-bore closure to remove the catalyst cartridge for loading and unloading. The reactor contains two catalyst beds, with the second one split into two parallel sections. Reactor feed gas passing between cartridge and shell is used to keep the pressure wall cool, and an inlet – outlet heat exchanger is located between first and second bed. A cold shot is installed for adjusting the inlet temperature of the first catalyst bed. A horizontal design with indirect cooling is also proposed in [829].

Figure 52. Kellogg horizontal intercooled ammonia converter

a) Inlet; b) Interbed heat exchanger; c) Bypass; d) Bed 1; e) Bed 2; f) Outlet

In the C. F Braun ammonia synthesis concept [772], [773], [819-822], separate vessels were used for the two catalyst beds in the original version. The feed – effluent heat exchanger was located between the first and second reactor vessels, and the second catalyst vessel was followed by a waste-heat boiler for high pressure steam. This basic concept was already introduced in the heyday of the quench converters and prior to the first energy crisis. In a later version three catalyst vessels [822-826] with boilers after the second and the third were used. The gas flow is axial and the mechanical design rather simple. Contrary to most converter designs, in which the pressure shell is kept below 250 °C by means of insulation or by flushing with cooler gas, the pressure vessel wall of the C. F. Braun reactors is at 400 °C, which is possible with modern steels in compliance with the Nelson diagram (see Section Material Considerations for Equipment Fabrication). Figure 53 shows the two-bed version of the C. F. Braun converter.

Figure 53. C. F. Braun converters with interbed heat exchanger and waste-heat boiler

a) Gas inlet; b) Feed – first bed effluent exchanger; c) Bypass for temperature control; d) First bed; e) Line to second bed; f) Second bed; g) waste-heat boiler (Borsig); h) Steam drum; i) Steam outlet; k) Gas outlet

To withstand the high outlet temperature level (450 – 500 °C) needed for the high-pressure boilers, a special design is employed to keep the outlet nozzle cool. C. F. Braun has devised a good solution by direct coupling the boilers and the exchanger to the converter.

Uhde has used three catalyst beds for capacities up to 2300 t/d (Fig. 54). The first two are accommodated in a single pressure vessel together with an inlet – outlet exchanger. Then a waste-heat boiler generating high-pressure steam cools the gas before it enters the second vessel containing the third bed, which discharges through a second external high-pressure boiler. The gas flow is in radial mode in all three catalyst beds.

Figure 54. Uhdes standard synloop configuration

a) Ammonia converter; b) Syngas compressor; c) Refrigeration

A new development is the Uhde dual pressure process [1343], [1351-1355], suited for very large capacities. The syngas with 110 bar from the low-pressure casing of the compressor is fed to a three-bed, intercooled, once-through converter which can produce a third of the total ammonia yield. From the effluent about 85 % of the ammonia produced is removed from the gas before it is compressed in the high presure casing to 210 bar to enter the well-known Uhde two-vessel-three-bed combination as described above. Figure 55 shows the Uhde dual pressure concept. The first plant based on this concept with a capacity of 3300 t/d will come on stream 2006 in Al-Jubail, Saudi Arabia (Safco IV). This is so far world-wide the largest capacity in a single synthesis (see also Single-train Capacity Limitations – Mega-Ammonia Plants).

Figure 55. Uhde dual pressure ammonia synthesis concept

Topsøe has now introduced a hot-wall converter with only one catalyst bed and no internal heat-exchange equipment, similar to C.F. Braun, but with radial flow. Three of these converters can be combined with an external heat exchanger and two high-pressure boilers to give an arrangement as described for Braun. This Topsøe Series 50 converter, can also be combined with the Series 200 reactor and two external high-pressure boilers to attain the configuration as described for Uhde (Topsøe Series 250).

Kellogg has developed for its ruthenium catalyst based KAAP ammonia process [406], [469] a special converter design. Four radial flow beds are accommodated in a single pressure shell with intermediate heat exchangers after the first, second and third bed. The first bed is loaded with conventional iron catalyst, the following ones with the new ruthenium catalyst. Figure 56 is a simplified sketch of the synthesis loop of the KAAP Figure 57 shows the internals of the KAAP converter [1375].

For revamps Kellogg has also proposed a two-bed version completely loaded with ruthenium catalyst to be placed downstream of a conventional converter [470].

Optimizing the Temperature Profile and Bed Dimensions in Multibed Converters. With closer approach to equilibrium, the volume of catalyst required in the individual beds increases, requiring greater total catalyst volume and appropriate changes in the catalyst bed dimensions. The literature has frequently treated the problem of optimizing both the distribution of catalyst volume between a given number of beds and the bed inlet temperatures [713], [715], [740], [795, 799, 802, 806]. Reference [812] examines optimizing the temperature profile in a given four-bed quench converter. For additional literature on this important issue in converter layout and design, see also Converter Design..

4.5.3.3. *Waste-Heat Utilization and Cooling*

The reaction heat of ammonia synthesis is 46.22 kJ/mol at STP, which corresponds to 2.72 GJ per tonne NH_3. Utilization of this heat at the highest possible temperature for generating high-pressure steam is a major contribution to the high total energy efficiency of modern ammonia plants [830]. Early converters, operating at about 300 bar, equipped with a lower heat exchanger for raising the inlet temperature for the (first) catalyst bed to the ignition temperature (ca. 400 °C) , received the converter feed at about ambient temperature and therefore had outlet temperatures of ca. 250 °C (ca. 15.5 °C per mol % of ammonia formed).

Initially there was practically no heat recovery, and nearly the total heat content of the gas down to ambient temperature and thus the reaction heat was transferred to cooling water. Subsequently plants were modified to use this heat to some extent, but the low temperature level allowed only boiler feed water heating and generation of low-pressure steam (ca. 20 bar). In some instances, water circulation was installed to use this heat in other plants or production steps. As for any type of converter the outlet temperature rises with increasing inlet temperature (ΔT is determined by the degree of conversion), in further developments an additional heat exchanger for converter feed versus the converted gas was installed, downstream of the above-mentioned heat recovery. In this way the temperature level at which heat could be recovered was increased, ultimately to the point where the inlet temperature to waste-heat recovery is equal to the outlet temperature of the last catalyst bed. In practice this corresponds to moving the lower heat exchanger (which in multibed converters exchanges feed to the first catalyst bed against effluent from the last bed) partially or completely to a position outside of the converter and downstream of the waste-heat recovery installation. In this way the waste-heat downstream of the synthesis converter in modern plants is available in the temperature range around 480 to 290 °C. The steam pressure, formerly 100 bar, has now been raised to 125 bar, which means that the gas can be cooled in the boiler to ca. 350 °C ; the remaining recoverable heat is used for boiler feed water heating.

The trend followed in newer plants is to increase conversion per pass with the result of higher ammonia outlet concentrations and lower outlet temperatures from the last bed. However, as optimum energy efficiency of the whole ammonia plant requires maximum high-pressure steam generation, part of the heat must be recovered before the reaction is completed in the reactor system. This can be accomplished [807], [808], [830], [831] by using three catalyst beds in separate pressure vessels with boilers after the second and the third vessel and an inlet – outlet heat exchanger for the first catalyst bed.

Advanced ammonia concepts produce as much as 1.5 t of high-pressure steam per tonne of ammonia, which correspond roughly to 90 % of the standard reaction enthalpy. Figure 58 is a temperature – enthalpy diagram for a converter system corresponding to the original C. F. Braun arrangement. High-pressure steam (113 bar, 320 °C) is generated after the second catalyst bed.

Appropriate designs of waste-heat boilers are described in Waste-Heat Boilers for High-Pressure Steam Generation.

4.5.3.4. *Ammonia Recovery from the Ammonia Synthesis Loop*

In all commercial plants ammonia is recovered from the synthesis loop by cooling the synthesis gas to condense the ammonia under synthesis pressure. The liquid ammonia product is separated from the gas, which is recycled. Arrangement and location of the ammonia separator(s), recirculation compression, addition of make-up gas and extraction of purge gas are discussed in Section Synthesis Loop Configurations; see also Figure 34).

In older high-pressure synthesis loops (> 450 bar) cooling by water and or air is sufficient to obtain the required low residual ammonia concentration in the gas. In modern plants, which operate at moderate pressures, the cooling has to be supplemented by refrigeration, for which a mechanical ammonia refrigeration cycle, with one or more temperature levels is generally used. Refrigeration down to – 25 °C is used, which with inclusion of the necessary temperature difference in the chiller requires ammonia evaporation at about atmospheric pressure. The amount of ammonia vaporized (and consequently reliquefied by compression and water or air cooling) can be substantial. At a loop pressure in the range 100 to 150 bar the quantity of reliquefied ammonia may be twice the ammonia product flow.

The liquid ammonia of the high-pressure separator is flashed to about 20 bar, whereby the majority of the dissolved gases are released in the let-down vessel. This gas is normally used as a fuel, preferably after removal of ammonia vapor to avoid NO_x formation in the combustion furnace.

The ammonia from the let-down vessel may be sent directly to downstream users or flashed further to atmospheric pressure for storage in a cold tank. All ammonia vapors removed from flash gases and from purge gas by water scrubbing can be recovered as pure liquid product by distillation if there is no direct use for the aqueous ammonia.

Absorption refrigeration with aqueous ammonia instead of a mechanical refrigeration system [832], [839], [845], [847], [853], [855] did not find widespread application.

Although ammonia condensation was already used in HABER's lab-scale ammonia plant and in early pilot plants of BOSCH, the first commercial units of BASF used ammonia absorption in water to remove the product from the cool synthesis loop gas, because various technical problems were encountered with refrigeration at that time. It was only in 1926 that ammonia condensation was introduced in the Haber – Bosch plants. In the early 1920s LUIGI CASALE successfully used condensation for his first plant. Water cooling was sufficient on account of the very high synthesis pressure.

Recovery of ammonia by water scrubbing offers the advantage of achieving a very low residual ammonia content, but the drawback is that the whole recycle gas has to be dried afterwards and in addition distillation of aqueous ammonia is necessary to yield liquid ammonia. Nevertheless the scrubbing route was again proposed for a synthesis loop to be operated under extremely low pressure (around 40 bar) [862]. Snam Progetti [288], [866], [867] has proposed removing the ammonia from the loop gas at ambient temperature down to 0.5 mol % by absorption in dilute aqueous ammonia.

The extent to which the ammonia concentration in the gas can deviate from that expected for ideal behavior can be seen from Tables 4 and 5. For example, at 30 bar the ammonia vapor pressure according to Table 4 is 1.167 bar, corresponding to 5.84 mol % at the total pressure of 20 bar. In contrast, Table 5 gives the ammonia concentration in a 1/3 nitrogen/hydrogen mixture at 20 bar total pressure as 9.8 mol %.

4.5.3.5. *Inert-Gas and Purge-Gas Management*

Apart from nitrogen and hydrogen, the fresh make-up gas supplied to the synthesis loop usually contains small quantities of inert gases. These include methane (from gas generation), argon (from the process air), and helium (from the natural gas). Because they are inert , they tend to concentrate in the synthesis loop and must be removed to maintain the loop material balance. A portion of the inert gases dissolves in the liquid produced in the ammonia separator. Table 6 gives a rough approximation of the extent to which these inerts are dissolved. Figure 2 gives vapor – liquid equilibrium ratios for use in making precise calculations of the dissolved quantities of inerts. If the synthesis gas pressure is high, for example, 300 bar), and the inert gas concentration in the synthesis loop make-up gas low enough, for example, under 0.2 vol % [868], then dissolution in the product ammonia suffices to remove the inerts from the synthesis loop.

With a higher inert gas content in the make-up gas this method is not applicable, because the required partial pressure of the inert gas at equilibrium in the loop gas would become so high that a synthesis under moderate pressure would be virtually impossible. So, in addition to removal as dissolved gases (flash gas), inerts have also to be removed from the gas phase by withdrawing a small purge-gas stream from the loop. At the same time expensive synthesis gas is also lost from the loop, which lowers the ammonia yield. Therefore, determining the appropriate inert gas concentration requires a precise economic calculation.

A high inert gas level has various drawbacks. It decreases the specific converter performance by reducing the hydrogen and nitrogen partial pressures. The gas recycle flow is increased by the amount of inert gas. Piping and equipment must correspondingly be increased in size, and the associated power consumption for recycle gas increases. Moreover, there is an unfavorable effect on condensation of the ammonia product. Because of the dilution, less ammonia can be condensed from the recycle synthesis gas by less expensive air or water cooling or higher temperature level refrigeration.

There are several possibilities for reducing the losses associated with the purge gas. The most capital-intensive method consists of feeding the purge gas to a second synthesis loop operating at a slightly lower pressure [869], [870]. As this loop can operate at a very high inert level (40 % or more), only a very small final purge stream is necessary and no recompression is needed. Up to 75 % of the hydrogen from the first-loop purge stream can be recovered. This system has the advantage that nitrogen is also recovered, but it is too expensive for use in modern plants and revamps. For this reason other methods have been developed.

Hydrogen Recovery by Cryogenic Units [848]. Ammonia is first removed from the purge gas by cooling or in a water wash operating at 7.5 MPa (75 bar). Molecular sieve adsorbers then eliminate moisture and traces of ammonia (Fig. 59). The dry, ammonia-free purge gas from the adsorbers next enters the cold box. Heat exchange with cold product hydrogen fraction and with gas rejected to fuel cools the purge gas to a temperature of about –188 °C (85 K). Partial condensation liquefies methane and argon as well as some of the nitrogen and helium. These are removed in a separator, leaving a hydrogen-rich gas.

Figure 59. Simplified flow diagram of cryogenic hydrogen recovery unit

a) Molecular sieve adsorbers; b) Heater; c) Plate-fin exchanger; d) Separator; e) Ammonia-free purge gas; f) Fuel gas to reformer burners; g) Hydrogen product to syngas compressor; h) NH_3 refrigerant

The liquid flows through a control valve, reducing its pressure, and into a brazed aluminum (plate-fin or core-type) heat exchanger. The hydrogen-rich gas also flows into the same exchanger (in separate passages) where the vaporizing liquid and the hydrogen are warmed by cooling the entering purge gas. Liquid ammonia from the ammonia plant may be used to provide additional refrigeration, especially at plant startup.

The warm hydrogen-rich gas flows back to the suction side of the second stage of the synthesis gas compressor (6.5 – 7 MPa). About 90 – 95 % of the hydrogen and 30 % of the nitrogen in the purge gas can be recovered.

The remaining gas, with a high concentration of inerts, serves as fuel for the primary reformer. After heating in a preheater, a portion serves to regenerate the molecular sieves and then likewise flows to reformer fuel.

Cryogenic hydrogen recovery units are supplied by firms such as Costain Engineering (formerly Petrocarbon Development) [782], [849-851], [924], [936-941], Linde [852], and L'Air Liquide, among others. Reference [788] reports on the changes in operating conditions of an ammonia plant resulting from the operation of a cryogenic hydrogen recovery unit.

Hydrogen Recovery by Membrane Separation. The Monsanto Prism membrane separator system uses selective gas permeation through membranes to separate gases. This principle has been applied to separating hydrogen from other gases [942-945] (⟶ Membranes and Membrane Separation Processes). The membranes are hollow fibers with diameters of about 0.5 mm. The fiber is a composite membrane consisting of an asymmetric polymer substrate and a polymer coating. The design of a single separator module (length, 3 – 6 m; diameter, 0.1 – 0.2 m) resembles a shell and tube heat exchanger. A bundle with many thousands of hollow fibers is sealed at one end and embedded in a tubesheet at the other. The entire bundle is encased in a vertical shell (Fig. 60).

Figure 60. Gas separator module

a) Nonpermeate gas outlet; b) Fiber bundle plug; c) Hollow fiber; d) Separator (length, diameter, and number of separators determined by ammonia process); e) Coated carbon steel shell; f) Feed stream of mixed gases; g) Permeate gas outlet

The purge gas is water scrubbed at 135 – 145 bar, reducing the ammonia concentration to less than 200 ppm. The scrubbed purge gas is heated to 35 °C and sent directly to the Prism separators. Trace concentrations of ammonia and water vapor in the gas stream pose no problem to the membrane. Therefore, a dryer system is not required.

The gas stream enters the separator on the shell side, i.e., the outside of the hollow fibers. Hydrogen permeates through the wall of the fibers. Hydrogen-rich permeate gas flows down the bore of the fiber and through the tubesheet and is delivered at the bottom of the separator. The remaining (nonpermeating) gases, nitrogen, methane, and argon, are concentrated on the shell side, recovered through the top and pass to the next separator module. Several separators operate in series. The rate of permeation decreases across a bank of separators as the hydrogen partial pressure differential across the membrane approaches zero. Therefore, a second bank of separators with lower pressure on the tube side is used to increase the hydrogen recovery. Of the recovered hydrogen, 40 – 70 % leaves the first bank of separators at 7 MPa (70 bar) and is returned to the second-stage suction of the syngas compressor. The second bank permeate hydrogen is recovered at 2.5 – 2.8 MPa (25 – 28 bar) and returned to the first-stage suction of the syngas compressor. Overall hydrogen recovery is 90 – 95 %. The remaining nonpermeate gas stream normally flows to primary reformer fuel.

The main advantages of the Prism separator system are simplicity, ease of operation, and low maintenance. Reference [946] compares membrane and cryogenic separation units for a large ammonia plant.

For further literature on gas separation by membranes, see [854], [856], [857], [947-949], [950].

Membrane technology is also offered by other licensors; an example is the Polysep Membrane System of UOP [858]. In addition to the systems based on hollow fibers, membrane modules have been developed in which the membrane is in the form of a sheet wrapped around a perforated center tube using spacers to separate the layers. The raw gas flows in axial direction in the high pressure spacer and the permeate is withdrawn in the low pressure spacer. Linde, for example, offers such a module under the name Serarex [859], [860].

Hydrogen Recovery by Pressure Swing Adsorption. Pressure swing adsorption on zeolite molecular sieves (PSA) (see Section Gas Purification) may be also used for hydrogen recovery from purge gas [663]. The process, originally developed by Union Carbide under the name HYSIV, is now marketed as Polybed PSA by

UOP [858], [951-953]. PSA technology is also offered by Linde and other companies. If required, the process also offers the possibility to supply pure hydrogen from the purge gas for other uses. PSA units usually operate at adsorption pressures of 20 – 30 bar and achieve recovery rates higher than 82 % for hydrogen and 20 % for nitrogen. Carbon-based adsorbents for pressure swing adsorption have also been investigated [951], [952] and a process developed by Bergbau-Forschung [953] is offered by Costain.

Hydrogen Recovery Using Mixed Metal Hydrides. A proprietary hydrogen separation process utilizing the reversible and selective adsorption capability of mixed metal hydrides has been proposed. The hydride, such as $LaNi_5$, FeTi, or Mg_2Cu, is in the form of ballasted pellets. The ballast material serves as a heat sink to store the heat of adsorption. Subsequently, this is used to supply the heat of desorption. The ballast also is the binder for the pellets, preventing attrition. Each type of metal hydride is susceptible to certain contaminants. Therefore, selection of the metal hydride must be based on the analysis of the gas to be treated. No ammonia removal step is required upstream of the unit. The system yields 99 mol % hydrogen product at a recovery efficiency of 90 – 93 % [954], [860], [861]. No commercial installations are known to be in operation in ammonia production processes.

Argon Recovery from Ammonia Purge Gas. The waste gas from hydrogen recovery plants is more highly enriched in argon than the purge gas. If potential markets for argon exist, then it may be possible to supplement the hydrogen recovery plant with one for recovering argon. Cryogenic argon recovery from ammonia purge gas is discussed in [955-957]. Typical argon recoveries are in excess of 90 %, with a purity of 99.999 %.

4.5.3.6. *Influence of Pressure and Other Variables of the Synthesis Loop*

The influences of individual parameters can be summarized as given in [846, p. 231]:

- Pressure: increasing pressure will increase conversion due to higher reaction rate and more favorable ammonia equilibrium.
- Inlet temperature: there are two opposed effects as increasing temperature enhances reaction rate but decreases the adiabatic equilibrium concentration.
- Space velocity: increasing the space velocity normally lowers the outlet ammonia concentration, but increases total ammonia production.
- Inert level: increasing the inert level lowers the reaction rate for kinetic and thermodynamic reasons (Section Kinetics).
- Hydrogen/nitrogen ratio: a true maximum reaction rate for a certain H/N ratio; at lower temperatures the maximum lies at lower H/N ratios (Section Kinetics). Position of the maximum also depends on the space velocity values (Section Formation of Ammonia in the Converter).
- Recycle rate: at constant pressure and production rate, the consequence of higher recycle rate is a lower ammonia concentration. In this case the difference to the equilibrium concentration and thus the reaction rate increases with the result that less catalyst is required. However, the temperature level for waste-heat recovery decreases and with lower temperature differences, larger heat exchanger surface areas become necessary and the cross sections of piping and equipment have to be enlarged on account of the higher gas flow.
- Separator temperature: together with pressure and location of make-up gas addition, the temperature of the ammonia separator determines the ammonia concentration at the converter inlet. A lower temperature means lower ammonia concentration, which translates into either a lower catalyst volume or a higher conversion.
- Catalyst particle size (Section Particle Size and Shape): smaller catalyst particles give higher conversion because of lower diffusion restrictions (higher pore efficiency)

The question of the best synthesis pressure is rather a difficult one and the answer is extremely dependent on optimization parameters such as feedstock price, required return on investment, and site requirements. In principle it is possible to calculate the minimum amount of mechanical work needed in the synthesis loop. If plots of kilowatt hours versus synthesis pressure for make-up gas compression, recycle, and refrigeration are superimposed the result will be a minimum, for which a value of 155 bar is reported in [863], [864]. The result is strongly dependent on assumed boundary conditions, and other studies came to higher values in the range 180 – 220 bar. However, such diagrams should be interpreted with care. First, this type of plot is strongly influenced by the catalyst activity, and thus by any factors that affect it, such as grain size and minimum possible temperature for the first bed, and especially the equilibrium temperature of the last bed [865]. Second, this approach considers only the mechanical energy and ignores completely the recovered energy of reaction, its energy level, and its impact on the energy balance of the complete ammonia plant. Third, the temperature attainable at a given site by air- or water cooling will affect the refrigeration duty. And fourth, the type of front end can profoundly alter the result. The front-end pressure determines the suction pressure of the synthesis gas machine. In a plant based on partial oxidation with an operating pressure of 80 bar, less than half as much energy is needed to compress the make-up gas to 180 bar, for example, as in a steam reforming plant with a suction pressure of only 25 bar.

Thus the problem of choosing the best synthesis pressure is complex because not only does the entire energy balance have to be examined, but also the mechanical design and the associated investment costs. For an actual project, the costs for energy (i.e., the feedstock) have to be weighed against investment. With the exception of some older processes which used extremely high pressures (Casale, Claude) a pressure of around 300 bar was common for the old multistream plants operated with reciprocating compressors. The centrifugal compressor is one of the most important features of single-train ammonia plants. The first of these plants, with a capacity of 600 t/d, were built in the mid-1960s and the maximum attainable synthesis pressure was restricted to ca. 150 bar by technical limitations of the centrifugal compressor, which needed a minimum gas flow (see also Section Compression). Of course, at current plant sizes of 1200 – 2000 t/d this constraint is no longer of importance. These plants usually operate in the pressure range of 170 – 190 bar and it is a confirmation of the argumentation presented above that the different pressures are not reflected in the overall energy consumption of the complete ammonia plant. Analysis of the effects of various parameters on the energy consumption of the synthesis loop are also reported in [807], [808]. At constant equilibrium temperature for the effluent from the last bed (constant ammonia concentration) energy consumption of the loop was found to be almost independent of pressure in the range of 80 – 220 bar [865].

4.5.3.7. *Example of an Industrial Synthesis Loop*

Figure 61 is an example of modern ammonia synthesis loop (Krupp – Uhde) with two converter vessels and three indirectly cooled catalyst beds producing 1500 t/d NH_3 at 188 bar.

Figure 61. Example of a synthesis loop for 1500 t/d NH_3 (Krupp – Uhde)

11	374	38	3.25	5.22	90.20	2.86	1.72	0.00	
12	8041	35	18.20	24.93	73.54	1.16	0.37	0.00	

The gas enters the converter (a) at 295 °C and is subsequently heated in the internal heat exchanger to 390 °C before it enters the first catalyst layer. The outlet gas from the first layer then passes through the aforementioned heat exchanger and enters the second bed, after which the gas leaves the converter with 469 °C and

passes a waste-heat boiler generating 125 bar steam. The inlet gas of the second vessel, which accommodates the third catalyst bed, has a temperature of 401 °C and the outlet enters a further waste-heat boiler generating 125 bar steam.

4.6. Complete Ammonia Production Plants

The previous sections mainly considered the individual process steps involved in the production of ammonia and the progress made in recent years. The way in which these process components are combined with respect to mass and energy flow has a major influence on efficiency and reliability. Apart from the feedstock, many of the differences between various commercial ammonia processes lie in the way in which the process elements are integrated. Formerly the term ammonia technology referred mostly to “ammonia synthesis technology” (catalyst, converters, and synthesis loop), whereas today it is interpreted as the complete series of industrial operations leading from the primary feedstock to the final product ammonia.

The major determinant for process configuration is the type of feedstock, which largely governs the mode of gas generation and purification. The other important factor is the plant capacity, which, together with consumption and costs of feedstock and energy, is decisive for the production economics. An important development was the concept of single-train plants, first introduced for steam reforming based production by M.W. Kellogg in 1963 with a capacity of 600 t/d. Before then maximum capacities had mostly been about 400 t/d, with several parallel trains in the synthesis gas preparation stage and the synthesis loop. Today world-scale plants have capacities of 1200 – 2000 t/d. The lowest capital cost and energy consumption result when steam reforming of natural gas is used. In addition site requirements can influence the layout considerably. In contrast to a stand-alone plant, ammonia production at a developed industrial site may import and/or export steam and power, which affects the total energy consumption.

With the exception of the Koppers – Totzek coal gasification process, which operates at near atmospheric pressure, all modern gasification processes operate at elevated pressure. Steam reforming of light hydrocarbons at 30 – 40 bar and partial oxidation of heavy hydrocarbons at 40 – 90 bar are generally used.

4.6.1. *Steam Reforming Ammonia Plants*

4.6.1.1. *The Basic Concept of Single-Train Plants*

The innovative single-train concept, introduced in 1963 by Kellogg, was a technical and an economical breakthrough and triggered a tremendous increase in world ammonia capacity. No parallel lines, even for high capacity, and a highly efficient use of energy, with process steps in surplus supplying those in deficit, were the main features. Figure 62 shows a block flow diagram and the gas temperature profile for a steam reforming ammonia plant [1377].

Figure 62. Block diagram and gas temperature profile for a steam reforming ammonia plant

High level surplus energy is available from the flue gas of the reformer and the process gas streams of various sections, while heat is needed, for example, for the process steam for the reforming reaction and in the solvent regenerator of the carbon dioxide removal system. Because considerable mechanical energy is needed to drive compressors, pumps, and blowers, it was most appropriate to use steam turbine drives, since sufficient steam could be generated from the waste-heat. As the level was high enough to raise high-pressure steam (100 bar) it was possible to use the process steam first to generate mechanical energy in the synthesis gas compressor turbine before extracting it at the pressure level of the primary reformer. Table 25 lists all significant energy sources and sinks within the process.

Table 25. Main energy sources and sinks in the steam reforming ammonia process

Process section	Origin	Contribution
Reforming	primary reforming duty	demand
	flue gas	surplus
	process gas	surplus
Shift conversion	heat of reaction	surplus
CO_2 removal	heat of solvent regeneration	demand
Methanation	heat of reaction	surplus
Synthesis	heat of reaction	surplus
Machinery	drivers	demand
Unavoidable loss	stack and general	demand
Balance	auxiliary boiler or import	deficit
	export	surplus

The earlier plants operated at deficit, and needed an auxiliary boiler, which was integrated in the flue gas duct. This situation was partially caused by inadequate waste-heat recovery and low efficiency in some energy consumers. Typically, the furnace flue gas was discharged in the stack at rather high temperature because there was no air preheating and too much of the reaction heat in the synthesis loop was rejected to the cooling media (water or air). In addition, efficiency of the mechanical drivers was low and the heat demand for regenerating the solvent from the CO_2 removal unit (at that time aqueous MEA) was high. Maximum use was made of direct steam turbine drive, not only for the major machines such as synthesis gas, process air, and refrigeration, but even for relatively small pumps and blowers. The outcome was a rather complex steam system. Even after substitution of the smaller turbines by electric motors, the steam system in the modern plant is still a complex system as shown in Figure 64. Ammonia plant steam systems are described in [404], [406], [1318], [961-964].

The first generation of the single-train steam reforming plants is discussed in [420], [959], [960], [979], [980], [988], [995], and the required catalysts are reviewed in [539], [553], [999]. A survey of the development of the steam reforming concept through 1972 can be found in [969]. Other references which cover the development of the steam reforming before the introduction of the single-train concept (1940 to 1960) can be found in [404 p. 276].

The new plant concept had a triumphant success story. By 1969, 30 new Kellogg large single-train plants with capacities of 1000 t/d or more were in operation, and other contractors were offering similar concepts.

The decrease in energy consumption compared to the older technology was dramatic, and with the low gas prices at that time it is understandable that greater emphasis was placed on low investment cost, although there was a considerable potential for further reducing the energy consumption.

With the advent of the single-train steam reforming plants, it became standard for licensors and engineering contractors to express the total net energy consumption per tonne of ammonia in terms of the lower heating value of the feedstock used. The total net energy consumption is the difference between all energy imports (mainly feedstock) and all energy exports (mostly steam and/or electric power) expressed as lower heating value of the consumed feedstock, whereby electric power is converted with an efficiency of 25 – 30 % and steam is accounted for with its caloric value.

4.6.1.2. *Further Developments*

The significant changes in energy prices from 1973 onwards were a strong challenge to process licensors, engineering contractors and plant owners to obtain better energy efficiency. The overall energy consumption was reduced from around 45 GJ per tonne NH_3 for the first large single-train units to less than 29 GJ per tonne NH_3 (Table 26).

Table 26. Development of the net energy consumption of natural gas based steam reforming ammonia plants (real plant data) in GJ per tonne NH_3

Year	1966	1973	1977	1980	1991
Plant	A	B	C	D	E
Feed	23.90	23.32	23.48	23.36	22.65
Fuel, reformer	13.00	9.21	7.35	5.56	5.90
Fuel, auxiliary boiler	2.60	5.02	3.06	1.17	
Export					0.55
Total	39.50	37.55	33.89	30.18	28.00

Energy saving modifications are described in [288], [867], [970-978], [1000], [1001], [1005], [1018], [1025], [1030], [1254]. For catalyst improvements see [1395]. Some of the most important improvements compared to the first generation of plants are discussed below.

Feedstock Purification. In feedstock purification, mainly desulfurization, adsorption on active carbon was replaced by catalytic hydrogenation over cobalt – molybdenum or nickel – molybdenum catalyst, followed by absorption of the H_2S on ZnO pellets with formation of ZnS. By itself this measure has no direct influence on the energy consumption but is a prerequisite for other energy saving measures, especially in reforming and shift conversion.

Reforming Section. In the reforming section energy savings were achieved by several, often interrelated, measures, of which the most important are the following:

- Reduction of the flue gas stack temperature to reduce heat losses to the atmosphere [552]
- Avoiding excessive heat loss by better insulation of the reformer furnace
- Introduction of combustion air preheating [1018]
- Preheating the reformer fuel
- Increased preheat temperatures for feed, process steam and process air
- Increased operating pressure (made possible by using improved alloys for the reformer tubes and improved catalysts)
- Lowering of the steam to carbon ratio [1032]
- Shifting some reformer duty from primary to secondary reformer with the use of excess air [457], [458] or oxygen-enriched air [1276] in the secondary reformer, including the possibility of partially bypassing the primary reformer [1033], [1036]
- Installing a prereformer or rich-gas step is another possibility to reduce primary reformer duty and stack temperature of the flue gas [431-438], especially in LPG- and naphtha-based plants

A more recent development that breaks away from the usual plant configuration is to replace the traditional fired primary reformer with an exchanger reformer which uses the heat of the effluent of the secondary reformer [461-464], [466-469], [1035], [1036]. Also other applications have been reported in which flue gas [1035] heat from the fired reformer is used to perform a part of the reforming.

Shift Conversion. Improved LT shift catalysts can operate at lower temperatures to achieve a very low residual CO content and low byproduct formation. A new generation of HT shift catalysts largely avoids hydrocarbon formation by Fischer – Tropsch reaction at low vapor partial pressure, thus allowing lower steam to carbon ratio in the reforming section (see Section Carbon Monoxide Shift Conversion).

Carbon Dioxide Removal Section. In the carbon dioxide removal section the first generation of single-train plants often used MEA with a rather high demand of low-grade heat for solvent regeneration. With additives such as UCAR Amine Guard [603], [637], solvent circulation could be reduced, saving heat and mechanical energy. Much greater reduction of energy consumption was achieved with new solvents and processes, for example BASF aMDEA or Benfield LoHeat. Other hot potash systems (Giammarco Vetrocoke, Catacarb) and physical solvents (Selexol) were introduced (Section Gas Purification).

Final make-up gas purification was improved by removing the water and carbon dioxide traces to a very low level by using molecular sieves. Some concepts included cryogenic processes with the benefit of additional removal of methane and argon.

Ammonia Synthesis Section. In the ammonia synthesis section conversion was increased by improved converter designs (see Section Formation of Ammonia in the Converter), larger catalyst volumes, and to some extent with improved catalysts. The main advances in converter design were the use of indirect cooling instead of quenching, which allowed the recovery of reaction heat high pressure steam. Radial or cross-flow pattern for the synthesis gas instead of axial flow was introduced. All modern plants include installations for hydrogen recovery (cryogenic, membrane, or PSA technology; see Section Inert-Gas and Purge-Gas Management).

Machinery. Developments in compressor and turbine manufacturing have led to higher efficiencies.

- Gas turbine drive for a compressor and/or an electric generator combined with the use of the hot exhaust as combustion air for the primary reformer or raising steam (combined cycle) [705-709], [1039].
- Employing electric motors instead of condensation turbines [1040].
- Application of liquid and gas expansion turbines can recover mechanical work (e.g., let-down of the CO_2-laden solvent, liquid ammonia, purge and fuel gas).

Steam system and waste-heat recovery were improved by the following measures: increased pressure and superheating temperature of high-pressure steam; providing a part of the process steam by natural gas feed saturation [458], [603], [965-967]; inclusion of a steam superheater downstream of the secondary reformer [964], [968].

Process Control and Process Optimization. Progress in instrumentation and computer technology has led to increased use of advanced control systems and computerized plant optimization. Advanced control systems [981-987], [1133-1135] allow operating parameters to be kept constant in spite of variations in external factors such as feedstock composition or ambient or cooling water temperatures. These systems may be operated in open loop fashion (set values changed manually by the operator) or in closed fashion (set points automatically adjusted to optimum values by using a computer model with input of operational and economic data). Also plant simulation [989-992] is possible by using extensive computer models of complete plants. These models can simulate in real time the dynamic response to changes in operating parameters, plant upsets, etc. Such systems are used for off-line optimization studies and for operator training [993], [994].

The above list, by no means complete, is also a survey of options for plant revamps (Section Modernization of Older Plants (Revamping)). Quite a number of options can be found in papers presented at the "AIChE Annual Symposium Ammonia Plants and Related Facilities" giving practical experience and presenting case stories [1350].

Many of these elements are strongly interrelated with each other and may affect different sections of the plant concept. It is thus a demanding engineering task to arrive at an optimum plant concept, which can only defined by the conditions set by the feedstock price, the site influences, and the economic premises of the customer. An evaluation of the individual merits of the described measures in terms of investment and operational cost in a generalized form is not possible and can be done only from case to case in real project studies.

To illustrate the forgoing discussion of the concept of the single-train steam reforming plant, Figure 63 presents a modern low-energy ammonia plant with flow sheet and process streams (UHDE process).

4.6.1.3. *Minimum Energy Requirement for Steam Reforming Processes*

The energy saving measures described in Section Further Developments have considerably reduced the demand side (e.g., CO_2 removal, higher reforming pressure, lower steam to carbon ratio, etc.). On the supply side, the available energy has been increased by greater heat recovery. The combined effects on both sides have pushed the energy balance into surplus. Because there is no longer an auxiliary boiler which can be turned down to bring the energy situation into perfect balance, the overall savings usually could not be translated into further actual reduction of the gross energy input to the plant (mainly natural gas). In some cases this situation can be used advantageously. If the possibility exists to export a substantial amount of steam, it can be economically favorable (depending on feedstock price and value assigned to the steam) to deliberately increase the steam export by using additional fuel, because the net energy consumption of the plant is simultaneously reduced (Table 27).

Table 27. Increase of plant efficiency by steam export (GJ per tonne NH_3)

	Plant		Difference
	A	B	
Natural gas	27.1	32.6	+ 5.5
Electric power	1.1	1.1	
Steam export		– 6.4	– 6.4
Total energy	28.2	27.3	– 0.9

A reduction in gross energy demand, that is, a lower natural gas input to the plant, can only be achieved by reducing fuel consumption, because the actual feedstock requirement is determined by the stoichiometry. So the only way is to decrease the firing in the primary reformer, which means the extent of reaction there is reduced. This can be done by shifting some of the reforming duty to the secondary reformer with surplus air or oxygen-enriched air, although this makes an additional step for the removal of surplus nitrogen necessary. A more radical step in this direction is total elimination of the fired primary reformer by using exchanger reformers like the ICI GHR and the Kellogg KRES.

Based on pure methane, it is possible to formulate a stoichiometric equation for ammonia production by steam reforming:

$$CH_4 + \underbrace{0.3035\ O_2 + 1.131\ N_2}_{1.4345\ \text{air}} + 1.393\ H_2O \longrightarrow CO_2 + 2.262\ NH_3$$

$$\Delta H = -86\ \text{kJ/mol and}\ \Delta F = -101\ \text{kJ/mol at 25 °C}$$

From a mere thermodynamic point of view, in an ideal engine or fuel cell, heat and power should be obtainable from this reaction. Since real processes show a high degree of irreversibility, a considerable amount of energy is necessary to produce ammonia from methane, air and water. The stoichometric quantity of methane derived from the above reaction is 583 m^3 per tonne of ammonia, corresponding to 20.9 GJ per tonne NH_3 (LHV), which with some justification could be taken as minimum value. If full recovery of the reaction heat is assumed, then the minimum would be the lower heating value of ammonia, which is 18.6 GJ per tonne NH_3. Table 28 compares the specific energy requirement for ammonia production by steam reforming with the theoretical minimum.

Table 28. Specific energy requirement for ammonia production compared to the theoretical minimum

	GJ per tonne NH_3 (LHV)	% theory
Classical Haber – Bosch (coke)	80 – 90	(338 – 431)
Reforming, 0.5 – 10 bar (1953 – 55)	47 – 53	225 – 254
Reforming, 30 – 35 bar (1965 – 75)	33 – 45	139 – 215
Low energy concepts (1975 – 84)	29 – 33	139 – 158
Modern concepts (since 1991)	< 28	134
Stoichiometric CH_4 demand	20.9	= 100

Comparison of energy consumption figures without precise knowledge of design and evaluation criteria can be misleading. First of all the state of the ammonia product should be noted. Relative to the delivery of liquid ammonia to battery limits at ambient temperature, the production of 3 bar ammonia vapor at the same temperature would save 0.6 GJ per tonne NH_3, while delivery as liquid at – 33 °C would need an extra 0.3 GJ per tonne NH_3. The temperature of the available cooling medium has a considerable influence. Increasing the cooling water temperature from 20 to 30 °C increases energy consumption by 0.7 GJ per tonne NH_3 . A detailed energy balance, listing all imports and exports, together with the caloric conversion factors used for steam and power is needed for a fair comparison of plants. The beneficial effect of energy export to the net energy consumption is discussed above. Gas composition is also of some importance. Nitrogen content is marginally beneficial: 10 mol % nitrogen leads to a saving of about 0.1 GJ per tonne NH_3, whereas a content of 10 mol % carbon dioxide would add 0.2 GJ per tonne NH_3 to the total consumption value [996 p. 263].

Energy requirements and energy saving possibilities are also discussed in [288], [867], [1000], [1001], [1005], [1018], [1025], [1030], [1254].

The energy consumption figures discussed so far represent a thermodynamic analysis based on the first law of thermodynamics. The combination of the first and second laws of thermodynamics leads to the concept of ideal work, also called exergy. This concept can also be used to evaluate the efficiency of ammonia plants. Excellent studies using this approach are presented in [997 p. 258], [998]. Table 29 [997] compares the two methods. The analysis in Table 29 was based on pure methane, cooling water at 30 °C (both with required pressure at battery limits), steam/carbon ratio 2.5, synthesis at 140 bar in an indirectly cooled radial converter.

Table 29. Energy analysis of a low energy ammonia plant (GJ per tonne NH_3)

	HHV	LHV	Exergy
Input			
Natural gas consumption			
Reformer feed	24.66	22.27	23.28
Reformer fuel	7.49	6.78	7.08
Auxiliary boiler fuel	0.34	0.29	0.33
Total consumption	32.49	29.34	30.69
Losses			
Reforming	0,38	0,38	4,94
Steam generation	0.33	0.33	2.39
Shift, CO_2 removal, methanation	1.30	1.30	0.67
Synthesis	1.70	1.70	1.55
Turbines and compressors	6.50	6.50	0.54
Others (including stack)	1.30	0.68	0.46
Total losses	11.51	10.89	10.55
NH_3 product	20.98	17,12	20.14
Efficiency, %	64,60	58,40	65,60

Almost 70 % of the exergy loss in the process occurs in the reforming section and in steam generation. From conventional first law analysis it can be seen that almost all of the losses are transferred to the cooling water. As the analysis assumes water in liquid state, the LHV analyses in Table 29 is not completely balanced. For a perfect balance the heat of evaporation of water (as a fictive heating value) would have to be included.

4.6.1.4. *Commercial Steam Reforming Ammonia Processes*

Especially with ammonia processes based on steam reforming technology it has become a habit to differentiate between processes from various licensors and engineering contractors. This is not so much the case for partial oxidation plants (see Section Ammonia Plants based on Partial Oxidation). Strong competition together with increased plant size and the associated financial commitment has reduced the number of licensors and engineering contractors to a few companies capable of offering world-scale plants, often on a lump-sum turnkey basis. In some cases these companies sub-license their processes and special engineering know-how to competent engineering companies possessing no knowledge of their own in the ammonia field. There are also several smaller companies with specific and sometimes proprietary know-how which specialize in revamps of existing plants or small plant concepts.

In the following, each of the commercially most important processes is discussed in some detail and a shorter description of economically less important processes is given. The process configuration offered and finally constructed by a given contractor may vary considerably from case to case, depending on economic and site conditions and the clients' wishes. Thus plants from the same contractor and vintage often differ considerably. It is possible to categorize steam reforming plants according to their configuration in the reforming section:

1. Advanced conventional processes with high duty primary reforming and stoichiometric process air in the secondary reformer
2. Processes with reduced primary reformer firing and surplus process air
3. Processes without a fired primary reformer (exchanger reformer)
4. Processes without a secondary reformer using nitrogen from an air separation plant

In principle the amount of flue gas emitted should be related to the extent of fired primary reforming, but generalizations are questionable, because sometimes the plant layout, as dictated by site requirements, may considerably change the picture for the specific flue gas value.

4.6.1.4.1. Advanced Conventional Processes

Kellogg Low-Energy Ammonia Process [1042], [1043], [1254-1259], [1277]. The Kellogg process is along traditional lines, operating with steam/carbon ratio of about 3.3 and stoichiometric amount of process air and low methane slip from the secondary reformer. The synthesis pressure depends on plant size and is between 140 and 180 bar. Temperatures of the mixed feed entering the primary reformer and of the process air entering the secondary reformer are raised to the maximum extent possible with today's metallurgy. This allows reformer firing to be reduced and, conversely, the reforming pressure to be increased to some extent to save compression costs. An important contribution comes from Kellogg's proprietary cross-flow horizontal converter, which operates with catalyst of small particle size, low inlet ammonia concentration, and high conversion. Low-energy carbon removal systems (Benfield LoHeat, aMDEA, Selexol) contribute to the energy optimization.

When possibilities to export steam or power are limited, part of the secondary reformer waste-heat is used, in addition to steam generation, for steam superheating, a feature in common with other modern concepts. Proprietary items in addition to the horizontal converter are the traditional Kellogg reformer, transfer line and secondary reformer arrangement, waste-heat boiler, and unitized chiller in the refrigeration section.

According to Kellogg 27.9 GJ per tonne NH_3 can be achieved in a natural gas based plant with minimum energy export, but with export of larger quantities of steam this value could probably be brought down to about 27 GJ per tonne NH_3. Figure 65 shows a simplified flowsheet of the process [1259] with Selexol CO_2 removal systems (other options are, e.g., Benfield or BASF aMDEA).

Haldor Topsøe Process. In addition to technology supply, Haldor Topsøe also produces the full catalyst range needed in ammonia plants. The energy consumption of a basically classic plant configuration has been reduced considerably by applying systematic analysis and processes engineering. Descriptions and operational experience are given in [552], [433], [1018], [1049-1060].

Topsøe offers two process versions. The first operates at steam/carbon ratio of 3.3 and with rather high residual methane content from the secondary reformer. Shift conversion is conventional, the Benfield or Vetrokoke process is used for carbon dioxide removal, and the synthesis pressure depends on plant size ranging between 140 and 220 bar when the proprietary Topsøe two-bed radial converter S 200 is used. A simplified flowsheet is presented in Figure 66.

Figure 66. Haldor Topsøe's low energy process

a) Desulfurization; b) Primary reformer; c) Secondary reformer; d) Shift conversion; e) CO_2 removal; f) Methanation; g) Main compressor; h) Recycle compressor; i) Heat recovery; j) Converter

An actual plant has reported a consumption of 29.2 GJ per tonne NH_3 [1058].

The second version has a S/C ratio of 2.5 and shift conversion with medium- and low-temperature catalysts, both copper-based. For CO_2 removal Selexol or aMDEA is chosen. The synthesis is performed at 140 bar with a Topsøe two-bed S 200 radial converter, followed by a single-bed radial S 50 converter (S 250 configuration). After the converters, high-pressure steam is generated. An additional proprietary item is the side-fired reformer.

For this most energy-efficient concept a figure of 27.9 GJ per tonne NH_3 is claimed [1057].

Uhde Process. Uhde, in the ammonia business since 1928, markets a low-energy ammonia plant with classic process sequence and catalysts [1061-1068], [1343]. High plant reliability at competitive overall costs was a major objective. A process flow diagram together with the main process stream is presented in Figure 63.

Key features are the high reforming pressure (up to 43 bar) to save compression energy, use of Uhde's proprietary reformer design [1062] with rigid connection of the reformer tubes to the outlet header, also well proven in many installations for hydrogen and methanol service. Steam to carbon ratio is around 3 and methane slip from the secondary reformer is about 0.6 mol % (dry basis). The temperature of the mixed feed was raised to 580 °C and that of the process air to 600 °C. Shift conversion and methanation have a standard configuration, and for CO_2 removal BASF's aMDEA process (1340 kJ/Nm^3 CO_2) is preferred. Synthesis is performed at about 180 bar in Uhde's proprietary converter concept with two catalyst beds in the first pressure vessel and the third catalyst bed in the second vessel.

After each converter vessel high pressure steam (125 – 130 bar, up to 1.5 t per tonne NH_3) is generated (Uhde also offers its own boiler design in cooperation with an experienced boiler maker). Heat exchange between inlet and outlet of the first bed is performed in the first vessel, and gas flow in all beds is radial. When only a minimum of energy export (steam or power) is possible, the process heat from the secondary reformer outlet is partly used to raise high-pressure steam, and partly for superheating high-pressure steam. Refrigeration uses screw compressors with high operational flexibility and efficiency. Instead of the standard synloop Uhde offers the Dual Pressure Process for very large capacities (Fig. 55) (see Section Formation of Ammonia in the Converter). In this variant a once-through converter at lower pressure (100 bar), which produces about one third of the capacity, is followed by Uhde's standard loop (Fig. 54) at around 200 bar [1343], [1351-1355].

Achieved net energy consumption is about 28 GJ per tonne NH_3 and Uhde's engineers expect values of below 27 GJ per tonne NH_3 when a gas turbine and large steam export is included [1066].

LEAD Process (Humphreys & Glasgow, now Jacobs) [867], [1044]. The LEAD process is a highly optimized conventional approach with synthesis at 125 bar and two converter vessels, the first of which contains two catalyst beds with axial-flow quenching, while the second has a third bed with small particle size catalyst and radial flow. A consumption of 29.3 GJ per tonne NH_3 is claimed.

Exxon Chemical Process. The Exxon Chemical process [1070], [1071], was specifically designed for the company's own site in Canada and so far not built for third parties. It uses a proprietary bottom-fired primary reformer furnace and a proprietary hot potash carbon dioxide removal system with a sterically hindered amine activator. Synthesis loop and converter are licensed by Haldor Topsøe A/S. Synthesis is carried out at 140 bar in a Topsøe S-200 converter and total energy consumption is reported to be 29 GJ per tonne NH_3.

Fluor Process. The Fluor process [288], [845], [867], [1041] uses the proprietary propylene carbonate based CO_2 removal system with adsorption refrigeration using low level heat downstream of the low-temperature shift. Methanation and CO_2 removal are placed between the compression stages and thus operate at higher pressure. With a value of 32 GJ per tonne NH_3 [845] this is not really a low-energy concept.

Lummus Process. For the Lummus Process schemes [288], [867], [1045], [1047], [1048] a consumption of 29.6 [867] to 33.5 GJ per tonne NH_3 [1046] is quoted. In the synthesis section either an axial flow quench converter or a radial flow converter with indirect cooling is used. CO_2 removal is performed with a physical solvent, and there are no special features compared to other conventional process configurations.

Integrating the ammonia and urea process into a single train was proposed by Snam Progetti to reduce investment and operating costs [1097].

4.6.1.4.2. Processes with Reduced Primary Reformer Firing

Braun Purifier Process [457], [651], [654], [655], [867], [1069], [1072], [1073], [1261], [1262-1268]. Characteristic of the low-energy Braun purifier process (Fig. 67) is the reduced primary reformer duty, which is achieved by shifting a proportion of the reforming reaction to the secondary reformer by using about 150 % of the stoichiometric air flow. The excess nitrogen introduced in this way is removed after the methanation step in a cryogenic unit known as a purifier [1263], which also removes the methane and part of the argon. The result is a purer synthesis gas compared to conventional processes, and only minimal purge from the loop is required. A typical flow diagram of this process is shown in Figure 67.

Figure 67. The Braun purifier ammonia process

a) Sulfur removal; b) Primary reformer; c) Convection section; d) Secondary reformer; e) waste-heat boiler; f) Process air compressor; g) Gas turbine; h) High- and low-temperature shift converters; i) CO_2 removal solvent reboiler; k) CO_2 absorber; l) CO_2 desorber; m) CO_2 stripper; n) Methanator; o) Driers; p) Purifier heat exchanger; q) Expansion turbine; r) Purifier column; s) Synthesis gas compressor; t) Synthesis converters; u) waste-heat boiler; v) High-pressure ammonia separator; w) Ammonia letdown vessel; x) Ammonia recovery from purge gas

Synthesis is carried out in the proprietary Braun adiabatic hot-wall converter vessels (Fig. 53). Each catalyst bed (of which three are now used in newer plants [1262]) is accommodated in a separate vessel with an inlet – outlet heat exchanger after the first and high-pressure steam boilers after the following. The smaller furnace produces less flue gas and consequently less waste-heat, which makes it easier to design a balanced plant with no energy export. The lower reforming temperature allows a reduction of the steam/carbon ratio to about 2.75 without adverse effects on the HT shift, because of the less reductive character of the raw gas on account of its higher CO_2 content. In energy balanced plants, the use of waste-heat in the secondary reformer effluent is split between steam raising and steam superheating.

The concept shows great flexibility [1264] for design options. It is possible, for example, to aim for minimal natural gas consumption, even at the cost of importing some electric power. On the other hand, it is possible to improve the overall efficiency further by exporting a greater amount of energy. In this latter case it is advantageous to incorporate a gas turbine to drive the process air compressor. The hot exhaust (about 500 °C) of the turbine contains 16 – 17 mol % of oxygen and can serve as preheated combustion air of the primary reformer. In addition it is possible to include an electric generator to cover the plant demand and export the surplus. The C. F. Braun process can attain 28 GJ per tonne NH_3 in a balanced plant, but with steam export and realization of the available improvement possibilities a value of 27 GJ per tonne NH_3 seems feasible.

ICI AMV Process. The ICI AMV process [458], [1060], [1074-1086], [1404] also operates with reduced primary reforming (steam/carbon ratio 2.8) and a surplus of process air in the secondary reformer, which has a methane leakage of around 1 %. The nitrogen surplus is allowed to enter the synthesis loop, which operates at the very low pressure of 90 bar with an unusually large catalyst volume, the catalyst being a cobalt-enhanced version of the classical iron catalyst. The prototype was commissioned 1985 at Nitrogen Products (formerly CIL) in Canada, followed by additional plants in China. A flow sheet is shown in Figure 68

Figure 68. ICI AMV process

a) Desulfurization; b) Natural gas saturation; c) Process air compression; d1) Primary reformer; d2) Secondary Reformer; e) Boiler; f) High temperature shift; g) Low temperature shift; h) Selexol CO_2 removal; h1) CO_2 absorber; h2) Regenerator; i) Single stage compression; j) Methanation; k) Cooling and drying; l) Circulator; m) Hydrogen recovery; n) Ammonia converter; o) Refrigeration system

In the Canadian plant, only the air compressor is driven by a steam turbine, which receives the total steam generated in the plant and has an electric generator on the same shaft. All other consumers, including synthesis gas compressor, are driven by electric motors. Separate machines are used for make-up gas and recycle compression. The make-up gas compressor is located upstream of the methanator to make use of the compression heat to warm up the cold gas coming from the Selexol carbon dioxide scrubber.

A further key feature is that about half of the process steam is supplied by feed gas saturation. The synthesis converter is a three-bed design with quench between the first two beds and an exchanger after the second bed to raise the gas temperature of the feed to the first bed. Excess nitrogen and inerts (methane and argon) are removed by taking a purge gas stream from the circulator delivery and treating it in a cryogenic unit operating at loop pressure. The recovered hydrogen is returned to the circulator suction. Demonstrated efficiency is 28.5 GJ per tonne NH_3.

Foster Wheeler AM2 Process. The Foster Wheeler AM2 process [1033], [1087], also belongs to the group of processes that shift load from the primary to the secondary reformer, but differs from the preceding concepts in that only 20 – 50 % of the total feedstock is treated in the tubular primary reformer. The remaining feed is directly sent to the secondary (autothermal) reformer which operates with a high surplus of process air (up to 200 %) and a rather high methane slip of 2.75 % (dry basis). After conventional shift, further purification is performed by Selexol CO_2 removal, methanation, and molecular sieve drying. A cryogenic unit operating at synthesis pressure rejects the nitrogen surplus from the loop. An energy consumption of 29.3 GJ per tonne NH_3 is claimed.

Humphreys & Glasgow BYAS Process. The Humphreys & Glasgow (now Jacobs) BYAS process [1034], [1084], [1269] resembles the above-described processes in its principal process features: a considerable proportion of the feed is sent directly to the secondary reformer, bypassing the fired primary reformer; use of excess air in the secondary reformer; installation of a cryogenic unit as last step of make-up gas production to remove excess nitrogen, residual methane, and the majority of the argon. As a consequence the inert level in the loop can be kept rather low, with only a small withdrawal of purge gas. An energy consumption as low as 28.7 GJ per tonne NH_3 is claimed [1270]. The process is especially suited for revamps, where it allows plant capacity to be increased.

Jacobs Plus Ammonia Technology [1037] is especially tailored for small capacities in the 300 to 450 t/d range, with a load shift from primary to secondary reformer and use of excess process air. To produce a stoichiometric synthesis gas the surplus nitrogen has to be rejected in the final purification. This is done in a PSA unit, which receives the purge gas and part of the synthesis gas taken ahead of the methanation step. All nitrogen, methane, residual carbon oxides, and argon are adsorbed to give a stream of pure hydrogen. Hydrogen and the remainder of the synthesis gas downstream of methanation are mixed to achieve a 3:1 H_2:N_2 gas composition, with a lower inerts content than the synthesis gas after methanation. The consumption figure reported for a totally energy-balanced plant is 28.8 GJ per tonne NH_3, and with substantial steam export a value of 26.8 GJ per tonne NH_3 is claimed.

Montedison Low-Pressure Process. The Montedison low-pressure process [867], [1036], [1090], [1096] involves a split flow to two primary reformers. About 65 % of the feed – steam mixture flows conventionally through the radiant tubes of a fired primary reformer followed by a secondary reformer. The balance of the feed – steam mixture passes through the tubes of a vertical exchanger reformer. This exchanger reformer has a tubesheet for the catalyst tubes at the mixed feed inlet. There is no tubesheet at the bottom of the tubes, where the reformed gas mixes directly with the secondary reformer effluent. The combined streams flow on the shell side to heat the reformer tubes in a manner similar to that described for the M. W. Kellogg KRES reformer, see Section Processes Without a Fired Primary Reformer (Exchanger Reformer) and Feedstock Pretreatment and Raw Gas Production). The process air flow is stoichiometric. Synthesis is performed at 60 bar in a proprietary three-bed indirectly cooled converter with ammonia separation by water, from which ammonia is then recovered by distillation using low-grade heat. Other process steps are conventional. As driver of the process air compressor the installation of a gas turbine is suggested with use of the hot exhaust as preheated combustion air for the fired primary reformer. For this process, which has been tested in a 50 bar pilot plant, an energy consumption of 28.1 GJ per tonne NH_3 is claimed [1036].

Kellogg's LEAP Process. In the late 1970s Kellogg [288], [862], [867], [1089] proposed a process which extends the basic idea of the concept described above even further. The flow of the preheated gas stream mixture is split into three streams, with 47 % through catalyst tubes in the radiant section of the fired primary reformer, 12 % through catalyst tubes in the convection section, and 41 % through the tubes of an exchanger reformer heated by the effluent of a secondary reformer. It was intended to operate the ammonia synthesis at the pressure of the front end by using no synthesis gas compression or only a small booster. An enormous quantity of the classical ammonia synthesis catalyst would have been necessary, and for recovery of the ammonia from the loop a water wash with subsequent distillation was suggested, using low-level heat in an integrated absorption refrigerator. A consumption below 28 GJ per tonne NH_3 was calculated.

4.6.1.4.3. Processes Without a Fired Primary Reformer (Exchanger Reformer)

ICI LCA Process. The ICI LCA process [1091-1095] is a radical breakaway from the design philosophy of the highly integrated large plant used successfully for the last 25 years. Figure 69 shows a diagram of the so-called core unit which includes only the sections essential for ammonia production (up to 450 t/d). A separate utility section, shown in Figure 70, supplies refrigeration, steam, electricity, includes cooling and water-demineralization system, and, if needed, recovers pure carbon dioxide. Both figures show the configuration of the first two plants built at Severnside (UK) with a capacity of 450 t/d each.

Figure 69. ICI LCA process (core unit)

Figure 70. Arrangement of core units and utility section

Feed gas is purified in a hydrodesulfurization unit operating at lower than usual temperatures and passes through a saturator to supply a part of the process steam, while the balance is injected as steam. Heated in an inlet – outlet exchanger to 425 °C the mixed feed enters the ICI gas heated reformer (GHR) [461-463] at 41 bar, passing to the secondary reformer at 715 °C. The shell side entrance temperature of the GHR (secondary reformer exit) is 970 °C, falling to 540 °C at the exit of the GHR. Methane levels at the GHR exit and the secondary reformer are 25 % and 0.67 % respectively (dry basis). Overall steam to carbon ratio is 2.5 – 2.7. The gas, cooled to 265 °C in the inlet/outlet exchanger, enters a single-stage shift conversion reactor with a special copper – zinc – alumina-based catalyst that operates in quasi-isothermal fashion and is equipped with cooling tubes in which hot water circulates, whereby the absorbed heat is used for feed gas saturation, as described

above. CO_2 removal and further purification is effected by a PSA system, followed by methanation and drying.

Synthesis operates at 82 bar [1404] in a proprietary tubular converter loaded with a cobalt-enhanced formulation of the classical iron catalyst. Purge gas is recycled to the PSA unit, and pure CO_2 is recovered from the PSA waste gas by an aMDEA wash. Very little steam is generated in the synthesis loop and from waste gases and some natural gas in the utility boiler in the utility section (60 bar), and all drivers are electric.

The original intention was to design an ammonia plant which can compete with modern large capacity plants in consumption and specific investment, and, by means of lower energy integration, to achieve greater flexibility for start-up and reduced-load operation, needing minimum staffing. The basic plant features (GHR, isothermal shift, and synthesis) can in principal be applied to larger capacities. The flow sheet energy consumption is 29.3 GJ per tonne NH_3.

Kellogg, today Kellogg Brown and Root (KBR), offers several process schemes with use of its KRES exchanger reformer and its KAAP ammonia technology [467-470]. With including the Purifier (of C.F. Braun, later Braun and Root) KBR offers now the KAAPplusProcess [1329], [1330], [1379-1381] shown in Figure 71.

Figure 71. KBR KAAPplus Process

a) Air compressor; b) Sulfur removal; c) Process heater; d) Automatic reformer (ATR); e) Reforming exchanger (KRES); f) Condensate stripper; g) CO_2 absorber; h) Methanator; i) CO_2 stripper; j) Dryer; k) Expander; l) Feed/effluent exchanger; m) Condenser; n) Rectifier column; o) Synthesis gas compressor; p) KAAP ammonia converter; q) Refrigeration compressor; r) Refrigeration exchanger

Desulfurized gas is mixed with steam and then split into two streams in approximate ratio 2:1. These are separately heated in a fired heater. The smaller of the two enters the exchanger reformer at 550 – 550 °C, while the remainder is passed directly to the autothermal reformer at 600 – 640 °C. The exchanger reformer and the autothermal reformer use conventional nickel-based primary and secondary reforming catalysts, respectively. To satisfy the heat balance, the autothermal reformer operates with surplus of air. The required heat for the endothermic reaction in the tubes of the exchanger reformer comes from the gases on the shell side, comprising a mixture of the effluent from the autothermal reformer and the the gas emerging from the tubes. The shell side gas leaves the vessel at 40 bar. The purifier removes the nitrogen surplus together with residual methane and part of the argon.

Synthesis proceeds at about 90 bar in a four-bed radial-flow converter (Fig. 57) (hot-wall design) with interbed exchangers. The first bed is charged with conventional iron-based catalyst for bulk conversion and the others with Kellogg's high activity ruthenium-based catalyst, allowing an exit ammonia concentration in excess of 20 % to be obtained. The other process steps are more along traditional lines. The overall energy consumption claimed for this process can be as low as 27.2 GJ per tonne NH_3.

The LCA and KAAP*plus*Process are environmentally favorable because atmospheric emissions of both nitrogen oxides and carbon dioxide are dramatically reduced as there is no reforming furnace.

Chiyoda Process [1038]. In this process the traditional fired primary reformer is also replaced by an exchanger reformer and the heat balance requires excess air in the secondary reformer with the consequence of a cryogenic unit as final step in the make-up gas preparation to remove the surplus of nitrogen. Additionally, gas turbines are proposed as drivers for the process air compressor and synthesis gas compressor with the hot exhaust being used for steam generation and feed gas preheating.

Topsøe has described the lay-out for an ammonia plant based on fully autothemic reforming [1328].

4.6.1.4.4. Processes Without a Secondary Reformer (Nitrogen from Air Separation)

KTI PARC Process. The KTI PARC ammonia process [603], [1084], [1104], [1105], [1107-1110], [1260] uses the following process elements: air separation unit, classical primary reformer at 29 bar, standard HT shift, power generation in a Rankine cycle with CFC to generate electric power (optional), carbon dioxide removal (optional, only when pure CO_2 product is required), PSA, nitrogen addition, synthesis loop. In this concept four sections of the classical process sequence (secondary reforming, LT shift, CO_2 removal, methanation) can be replaced by the fully automatic high-efficiency PSA system, which has a proprietary configuration (UOP) in which nitrogen flushing enhances hydrogen recovery. The overall efficiency ranges from 29.3 to 31.8 GJ per tonne NH_3.

Linde LAC Process. The Linde LAC process [1112-1116] consists essentially of a hydrogen plant with only a PSA unit to purify the synthesis gas, a standard cryogenic nitrogen unit, and an ammonia synthesis loop. In principle it is similar to the PARC process, but designed for world-scale capacities. First application was for a 1350 t/d plant in India. Figure 72 compares the LAC process to a conventional one. If pure CO_2 is needed, it can be recovered by scrubbing the off-gas from the PSA unit at low pressure or, probably with better energy efficiency, by installing the CO_2 removal unit directly in the synthesis gas train ahead of the PSA system. The synthesis converter and loop are based on ICI and Casale know-how. According to Linde the process should consume about 28.5 GJ per tonne NH_3 or, with inclusion of pure CO_2 recovery, 29.3 GJ per tonne NH_3.

Figure 72. Comparison of Linde LAC process with a conventional process

Humphreys & Glasgow MDF Process (now Jacobs) [288], [665], [666], [1046], [1048], [1103], [1102], [1118], [1119]. This concept has a configuration similar to the Linde LAC process. Energy consumption with inclusion of pure CO_2 recovery (which is optional) is 32.8 GJ per tonne NH_3.

4.6.2. ***Ammonia Plants based on Partial Oxidation***

4.6.2.1. *Ammonia Plants Based on Heavy Hydrocarbons*

Although partial oxidation processes can gasify any hydrocarbon feedstock, on account of its higher energy consumption and investment costs, commercial use of this technology is restricted to the processing of higher hydrocarbons, often containing as much as 7 % sulfur. Where natural gas is unavailable or the heavy feedstock can be obtained at a competitive price, this gasification technology can be an economic choice.

There are two commercially proven partial oxidation routes for heavy feedstocks: the Shell process and the Texaco process. In contrast to the steam reforming, for which most contractors have their own proprietary technology for the individual process steps, the engineering firms which offer ammonia plants based on heavy hydrocarbons have often to rely for the individual process stages on different licensors. Lurgi, for example, has built very large capacity ammonia plants that use Shell's gasification process, its own proprietary version of the Rectisol process [1396], Linde's air separation and liquid nitrogen wash, and Topsøe's technology for synthesis converter and loop.

Independent, experienced engineering companies, not directly active in ammonia plant design may be used as general contractors to coordinate a number of subcontractors supplying the different technologies required. This is in line with the fact that the degree of energy integration is usually lower than in steam reforming technology, because in absence of a large fired furnace, there is no large amount of flue gas and consequently less waste-heat is available. Therefore, a separate auxiliary boiler is normally necessary to provide steam for mechanical energy and power generation. Nevertheless, some optimization has successfully reduced the overall energy consumption, for which in older installations values of around 38 GJ per tonne NH_3 were reported. More recent commercial bids quote values as low as 33.5 GJ per tonne NH_3.

The arguments presented above suggest describing the two principal routes, Shell and Texaco, which differ in the gasification process, rather than listing all individual contractor design approaches. Figure 73 shows the classical sequence of process steps for both cases.

Figure 73. Flow diagrams of ammonia production from fuel oil or heavy residues by the Shell (A) and the Texaco (B) process (standard configuration)

Processes Using Shell Gasification (e.g., Lurgi) [471], [477-485], [492]. A cryogenic air separation plant provides oxygen for the gasification and the nitrogen for the liquid nitrogen wash and for supplying the stoichiometric amount for the synthesis of ammonia. Oil enters the alumina-lined gasification vessel through a central jet in the burner nozzle. A substantial pressure drop is needed to ensure atomization of the oil and proper mixing with oxygen, fed through the annulus between the jet and the outer case of the burner nozzle. The temperature in the gasification vessel (generator) is between 1200 and 1400 °C, and the pressure between 35 and 65 bar.

The hot gas contains soot, formed because of insufficient mixing of the reactants, and fly ash. A waste-heat boiler, a proprietary item of the Shell process, raises 100 bar steam and cools the gas to 340 °C. Soot is removed from the raw gas in a two-stage water wash. Older installations used an elaborate technique to remove the soot from the water by extraction with naphtha and light oil to form soot pellets which could be burnt or recycled to the feed oil. In newer installations the carbon – water slurry is filtered off in automatic filters, and the moist filter cake is subjected to a controlled oxidation in a multiple-hearth furnace.

A selective Rectisol unit with methanol of about –30 °C as solvent is used to remove H_2S and COS (together with some CO_2) to less than 0.1 %. (see also ⟶ Gas Production – Types of Processes). The removed sulfur-rich fraction is sent to a Claus plant for recovery of elemental sulfur or converted to sulfuric acid. The gas is heated subsequently by heat exchange, supplied with steam in a saturator, and then fed to shift conversion, which proceeds stepwise with intermediate heat removal. The gas is cooled by a direct water cooler, and the hot water is recycled to the saturator.

A second Rectisol wash stage follows to remove CO_2 by absorption at –65 °C in methanol, which is regenerated by flashing and stripping. Molecular sieve adsorption then removes residual traces of methanol and CO_2. To remove residual CO a liquid nitrogen wash is applied for final purification with the advantage of also lowering the argon content in the make-up gas, which is adjusted by nitrogen addition to the stoichiometric ratio $N_2 : H_2 = 1 : 3$. Converter and synthesis loop configuration depend on the licensor chosen. Plant descriptions are given in [1106, 1111, 1117, 1120].

Processes Using Texaco Gasification (e.g., Foster Wheeler, Linde, Uhde). Temperatures in the generator are similar to those in the Shell process; units with operating pressures up to 90 bar are in operation [422], [486], [487-491]. Some modern installations (e.g., Linde) use pumps for liquid oxygen instead of oxygen compressors. In contrast to the Shell arrangement, oxygen enters the gasifier through the central nozzle of the burner, and oil is fed through the annular space between central nozzle and outer burner tube. Instead of a waste-heat boiler a direct water quench is applied for cooling the raw synthesis gas, which is subsequently scrubbed first in a Venturi scrubber and then in a packed tower to remove the soot. Texaco also offers a version operating with a waste-heat boiler instead of a water quench. Although this is preferable when producing CO-rich synthesis gases (e.g., methanol or oxogas), quench is thought to be more economical when hydrogen-rich gases are manufactured. Soot recovery from the water is performed by extraction with naphtha. The soot – naphtha suspension is mixed with feed oil, and the naphtha is distilled off and recycled to the extraction stage. The shift reaction uses a cobalt – molybdenum – alumina catalyst [417], [418], [554], [555], [556], [638] which is not only sulfur-tolerant but also requires a minimum sulfur content in the gas for proper performance. The conversion is subdivided into stages with intermediate cooling by raising steam. The following Rectisol process has a somewhat more elaborate configuration than the version used in the Shell route. The large amount of carbon dioxide formed in shift conversion lowers the H_2S concentration in the sour gas, and for this reason a special concentration step is required for methanol regeneration to obtain pure CO_2 and a fraction sufficiently rich in H_2S for a Claus plant or a sulfuric acid plant. The remaining process steps are identical with the Shell route. Figure 74 gives an example of a Linde flow diagram. Descriptions of plants using the Texaco process can be found in [416], [418].

Topsøe Process. A concept using enriched air instead of pure oxygen and methanation instead of a liquid nitrogen wash was proposed by Topsøe [1121], [1122]. A Shell gasifier with a waste-heat boiler or a Texaco generator with a quench are equally well suited to this process. After soot removal, shift conversion is performed on a sulfur-tolerant catalyst in several beds with intermediate cooling, leaving a residual CO content of 0.6 mol %. An appropriate process (Rectisol or amine based) removes the sour gases H_2S, COS, and CO_2, and this is followed by methanation. Make-up gas drying, compression, and synthesis loop have no special features. The anticipated energy consumption is 34.8 GJ per tonne NH_3. A basically similar synthesis gas preparation, but based on gasification with pure oxygen, is already used in large commercial plant in Japan [1274].

Foster Wheeler Air Partial Oxidation Process [1033], [1123] is a proposed modification of the Texaco gasification process. It is intended to operate at 70 bar with highly preheated air (815 °C) instead of pure oxygen. The synthesis gas purification train comprises soot scrubbing followed by shift conversion, acid gas removal (for

example Selexol), and methanation. The gas is dried and finally fed to a cryogenic unit, which removes the surplus nitrogen by condensation together with methane, argon, and residual carbon monoxide. The rejected nitrogen is heated and expanded in a turbine, which helps to drive the air compressor.

A major aspect in the design concept is the separation of nitrogen and oxygen. A conventional air separation plant is based on the fractional distillation of oxygen and nitrogen, which differ in boiling point by only 13 °C. In the cryogenic unit for the Foster Wheeler process a lesser quantity of nitrogen is separated from hydrogen with a much higher boiling point difference (57 °C). According to Foster Wheeler this leads to considerable saving in capital investment and energy consumption compared to the traditional approach using pure oxygen from an air separation plant and a liquid nitrogen wash for gas purification. A figure of 35.6 – 37.6 GJ per tonne NH_3 is claimed for heavy oil feedstock and 31.4 – 32.7 for natural gas as feedstock. A similar variant also using air instead of pure oxygen is offered by Humphreys & Glasgow (now Jacobs) [1281].

4.6.2.2. *Ammonia Plants Using Coal as Feedstock*

In the early days the entire ammonia industry was based on coal feedstock. Today coal or coke (including coke oven gas) are used as feed for only a smaller part of world-wide ammonia production. In 1990, for example, only 13.5 % of the world ammonia capacity used this raw material [502]. A newer statistic estimates a figure of 19 % for 2001 [1387]. But with the enormous increase of the natural gas prices in the USA the share of coal in the feedstock pattern of ammonia might become larger in the future (see Chapter Economic Aspects).

Apart from a few plants operating in India and South Africa, the majority of coal-based ammonia plants are found in China. Commercially proven coal gasification processes are Lurgi (dry gasifier), British Gas/Lurgi (slagging gasifier), Winkler/HTW, Koppers – Totzek, Shell, Texaco, and Dow, [493], [494], [495], [505]. So far only the Koppers – Totzek, Texaco, and Lurgi processes have been used commercially for ammonia production [493], [498-501], [503], [1250, 1331, 1332, 1334], [1387]. The Shell process, demonstrated commercially in another application with a capacity equivalent to a world-scale ammonia plant, is also a potential candidate for ammonia production processes.

In recent years little development work has been done on complete ammonia plant concepts based on coal. The traditional leading ammonia contractors have to rely on proprietary processes licensed from different companies, which similarly tend not to have specific ammonia technology of their own. Again, compared to a steam reforming plant, the degree of integration is considerably lower; power generation facilities are usually separate. Thus it is difficult to identify specific ammonia processes for the individual contractors and the following descriptions serve as examples, without striving for completeness.

The Koppers – Totzek Process gasifies coal dust with oxygen in the temperature range 1500 – 1600 °C at about atmospheric pressure. For a more detailed description of the gasification, refer to Section Feedstock Pretreatment and Raw Gas Production and [504-510]. The cooled gas, free of coal dust and fly ash, contains about 60 % of CO. The next step is compression to about 30 bar, followed by sulfur removal at –38 °C with chilled methanol (Rectisol process). Steam is added for the shift conversion, carried out stepwise with intermediate heat removal and with a standard HTS catalyst. A second Rectisol stage, operating at –58 °C and 50 bar, removes the CO_2, and the final purification step is a liquid nitrogen wash. Any of the well known converter and synthesis loop concepts may be used, with no purge or minimal purge, due to the practically inert-free make-up gas. Several plants are operating in South Africa [1124], [1125] and India [1126].

The atmospheric-pressure gasification is a considerable disadvantage of this process route, which substantially increases equipment dimensions and costs, as well as the power required for synthesis gas compression. An energy input of 51.5 GJ per tonne NH_3 (LHV) has been reported. According to [537], the atmospheric ACGP gasifier could lower the consumption to 44 GJ per tonne NH_3 (HHV).

Lurgi Process. Lurgi [494], [495], [526, 527, 529, 530], [528, 1127] offers a concept using its proprietary Lurgi dry bottom gasifier, described in Section Feedstock Pretreatment and Raw Gas Production. The moving-bed generator, which can handle any sort of coal (ash content may exceed 30 %), operates at 30 bar, and the product gas contains up to 15 % CH_4, higher hydrocarbons, troublesome phenolic material, and tars. After washing with process condensates to remove ash and dust, the gas is cooled further with recovery of waste-heat. Several process steps treat the separated gas liquor to recover tar, phenols, and some ammonia. Shift conversion, Rectisol process, and liquid nitrogen wash are the further operations in the production of make-up gas. The liquid nitrogen wash produces a methane-rich fraction, which is separately processed in a steam reformer, and the reformed gas rejoins the main stream at the Rectisol unit for purification. The gasification has a power consumption of 32 – 34 GJ per tonne NH_3, and steam generation consumes 18 – 22 GJ per tonne NH_3, resulting in a total energy consumption of 50 – 56 GJ per tonne NH_3.

The Texaco Coal Gasification Process [495], [518-525], [1128-1131], [1272], [1273] (see Section Feedstock Pretreatment and Raw Gas Production) originates from Texaco's partial oxidation process for heavy oil fractions and processes a coal – water slurry containing 60 – 70 % coal. A lock hopper system removes ash and glassy slag as a suspension from the quench compartment of the generator. The process can handle bituminous and sub-bituminous coal but not lignite. The further gas purification steps used to arrive at pure make-up gas correspond to those described for an ammonia plant using the Texaco partial oxidation of heavy oil fractions.

Ube Industries commissioned a 1000 t/d ammonia plant in 1984 using Texaco's coal gasification process [1274], [1275]. An energy consumption of 44.3 GJ per tonne NH_3 is stated, which is lower than the 48.5 GJ per tonne NH_3 quoted for another Texaco coal gasification-based ammonia plant [494].

4.6.3. *Waste-Heat Boilers for High-Pressure Steam Generation*

Because of its great influence on reliability and efficiency of all ammonia plants a special section for the generation of high-pressure steam seems to be appropriate. The operating conditions for the boilers are more severe than those normally encountered in power plants; on account of the high pressure on both sides the heat transfer rates and thus the thermal stresses induced are much higher.

In steam reforming plants, for example, the temperature of the gas from the secondary reformer has to be reduced from 1000 °C to 350 °C before entering the HT shift vessel. In earlier plant generations two boilers were usually installed in series, with a bypass around the second to control the inlet temperature for the HT shift. Common practice for a long time was to use a boiler with water tube design. A famous example is the Kellogg bayonet-tube boiler, applied in more than 100 plants. Besause of size limitations two parallel units were installed. For sufficient natural water circulation these boilers needed a steam drum at a rather high elevation and a considerable number of downcomers (feed water) and risers (steam/water mixture). An alternative tube-bundle design which can directly substitute the bayonet-tube internals was recently developed. This concept uses twisted tubes [1378].

In contrast fire-tube boilers are much better suited for natural circulation and the steam drum can sit in a piggyback fashion right on top of the boiler. This makes it possible to provide each boiler with its own separate steam drum, which allows a greater flexibility in the plot plan. In a fire-tube boiler, the inlet tubesheet and the tubesheet welds are exposed to the extreme temperature of the reformed gas, which creates rather large temperature gradients and therefore high expansive stress. A positive feature of the design, however, is that debris in feed water (mainly magnetite particles spalling from the water side of the tubes) can collect at the bottom of the horizontally mounted vessel without creating diffficulties and are removed easily by blowdown. Water-tube boilers, especially bayonet-types, are very sensitive in this respect, because the deposits may collect in the lowest and most intensively heated part of the tube. In an extreme case of scaling, this may restrict the water flow to the point where boiling occurs irregularly (film boiling). The risk is overheating and tube failure.

The key factor which allowed the use of fire-tube boilers after the secondary reformer was the development of thin-tubesheet designs. Thick tubesheets in this kind of service are too rigid and have too high a temperature gradient, and the resultant stress on the tube-to-tubesheet welds can lead to cracks. The inherent flexibility of thin tubesheets assists in dispersing stresses and reduces the risk of fatigue failure of the tube-to-tubesheet welds and tubesheet-to-shell welds. In all the various designs of this concept, the tubesheet is only 20 – 30 mm thick. The hot inlet channel and the tubesheet are shielded by a refractory layer, and the tube inlets are protected by ferrules. In one concept (Uhde [840], [841], Steinmüller [1337]) the flexible tubesheet is anchored to and supported by the tubes to withstand the differential pressure, which poses some restriction on the tube length. The tubesheet of Babcock-Borsig (today Borsig) [837], [1338], [1339] is reinforced by stiffening plates on the back side (Fig. 75). Both solutions have full penetration tube-to-tubesheet welds. Steinmüller's waste-heat boiler product line is now owned by Borsig. A critical analysis of the two concepts is given in [1340].

Figure 75. Reinforced tubesheet of the Borsig boiler

a) Tubesheeet; b) Tube; c) TIG welded root pass; d) Shell; e) Supporting ring; f) Stiffener plate; g) Anchor

In the synthesis loop boilers at the exit of the converter up to 50 % of the total steam is generated. As much as 1.5 t of steam per tonne ammonia, equivalent to 90 % of the reaction heat can be generated. For this service also fire-tube versions have been used, including Borsigs's thin-tubesheet design. But compared to the secondary reformer service, where the gas pressure is lower than the steam pressure, the conditions and stress pattern are different. In the synthesis loop boiler the opposite is the case with the result that the tubes are subjected to longitudinal compression instead of beeing under tension. Several failures in this application have

been been reported [842], [1341].

The thick-tubesheet concepts in various configurations are more generally accepted now. Proven U-type designs (Fig. 76) are available from Uhde [1342], [1353], Balcke – Dürr [833], [834], [1344], KBR [838], and Borsig [1347], [1345]. A horizontal synthesis waste-heat boiler was developed by Balcke – Dürr with straight tubes and thick tubesheets on both ends [835], [1346].

Figure 76. Uhde U-tube synthesis loop boiler

A special design is Borsig's hot/cold tubesheet. The hot and cold end of the tube are arranged alternately, so that a hot shank is always to a cold shank and vice versa. The advantage is that the tubesheet can kept below 380°C [836, 1318].

Waste-heat boilers in partial oxidation plants, which cool the exit gas of the generator from 1400 °C to around 350 °C, face additional difficulties. The gas contains soot and probably some fly ash particles. Very high gas velocities and appropriate design are necessary to prevent any deposition on the heat-exchange surfaces and to reduce the danger of attrition as well. A special design for Texaco gasifications (orginally by Schmidt'sche Heißdampf GmbH and Steinmüller GmbH) is offered now in an improved version (Fig. 77) by Borsig [1348]. Forced water circulation around the entrance nozzles helps to stand the high heat flux (700 kJ $m^{-2}s^{-1}$) at this location. The Shell process uses propretary designs (Fasel – Lentjes) [1349].

Figure 77. Borsig syngas waste-heat boiler for Texaco gasification

Additional information on waste-heat boilers is found in [762], [767], [404], [406], [1330]. Many papers on this subject were presented at the “AIChE Annual Symposia for Safety In Ammonia Plants and Related Facilities” [1350].

4.6.4. *Single-train Capacity Limitations – Mega-Ammonia Plants*

The principle of the economy of scale is well known in production processes. For ammonia plants a scale exponent 0.7 is widely used as a rule of thumb:

$$\mathrm{cost}_2 = \mathrm{cost}_1 \times (\mathrm{capacity}_2/\mathrm{capacity}_1)^{0.7}$$

The advantage of larger plants is not only the investment but also the reduction of fixed costs, such as labor, maintenance, and overhead expenses. But the simple formula should be handled with care because it is only valid as long as a given process configuration is scaled up and the dimensions of the equipment for very large capacities do not lead to disproportionate price increases. For example there may be fewer vendors or special fabrication procedures might become necessary. So the scale factor could increase for very large single-train capacities. Nevertheless the specific investment will decrease with the increase of capacity. On the other hand certain process developments like autothermal reforming and exchanger reforming could reduce the investment for the higher capacities.

For export-orientated plants at locations with cheap natural gas there is growing interest in very large capacities. Several studies [1317], [1355], [1381-1386] have been made by various contractors to investigate the feasibility and the size limitations for steam reforming plants. According to most of these studies a capacity of 5000 t/d seems to be possible. With a conventional process concept for the front end there is no restriction for producing syngas for 5000 t/d of ammonia. Steam reforming furnaces of the required size have already been built for other applications (methanol) and neccessary vessel diameters seem also to be fabricable. A limitation could be the synthesis compressor which can probably be designed for 4500 t/d only. The KBR KAAP process has there an advantage because of its low synthesis pressure. This also holds true for the Dual Pressure Process of Uhde, where just the loop which produces only two thirds of the ammonia is at high pressure whereas the once-through converter is at lower pressure. Another capacity limiting factor is pipe diameter in the synthesis section. The largest plant so far was built by Uhde in Saudi-Arabia. It has a capacity of 3300 t/d and came on-stream in 2006.

4.7. Modernization of Older Plants (Revamping)

With rising feedstock prices and hard competition in the market, many producers have looked for possibilities to “revamp” or modernize their older, less efficient plants so that they can stay competitive. Most revamp projects have been combined with a moderate capacity increase because some of the original equipment was oversized and only specific bottlenecks had to be eliminated, not entailing excessive cost. As the market possibilities for a company do not increase in steps of 1000 or 1500 t/d but slowly and continuously, such a moderate capacity addition will involve less risk and will be more economical than building a new plant.

For a revamp project first an updated base-line flow sheet of the existing plant should be prepared from which the proposed improvement can be measured [1002-1004]. Depending on the objective (energy saving and/or capacity increase) the following guidelines should be kept in mind: maximum use of capacity reserves in existing equipment; shifting duties from overtaxed units to oversized ones; if possible, simple modifications of existing equipment are preferable to replacement; the amount of additional equipment should be kept to a minimum [1003].

To give an exhaustive list or description of the individual modification options is beyond the scope of this article, but reviews on this subject and useful information are given in [1005-1017], [1098-1101], [1254], [1391], [1403]. Section Further Developments describes modifications that lower the energy consumption in newer plant generations compared to the first generation of single-train ammonia plants, and this also represents an overview of the revamp options for existing steam reforming plants.

Just a few of the frequently used revamp possibilities should be mentioned here. In steam reforming plants it is often possible to lower the steam/carbon ratio by using improved reforming catalysts and copper-promoted HT shift catalysts. More active LT shift catalysts lower the residual CO content, which will reduce H_2 loss (methanation) and inert content in the make-up gas. Drying of the make-up gas, addition of hydrogen recovery from purge gas, and installing a more effective CO_2 removal are other options. With the *aMDEA* system, which can be flexibly tailored to fit into existing process configurations, it is, for example, possible to simply replace the MEA solvent with the aMDEA solution, adjusting the activator concentration accordingly to achieve zero or only minor equipment modification. Also hot potash processes have been converted in this way to aMDEA.

Other measures, involving more additional hardware and engineering work, are introduction of combustion air preheating and reducing the primary reformer load. This latter option is used when the revamp objective is capacity increase and the primary reformer is identified as a bottleneck. One possibility is to increase the duty of the secondary reformer and use air in excess of the stoichiometric demand. Elegant variants of this principle are the *Jacobs BYAS process* [1034], [1084], [1269] and the *Foster Wheeler AM2 process* [1033], [1087], [1088]. Another method is to perform a part of the primary reforming in a pre-reformer [431-438] that uses low-level heat. Alternative methods to enlarge the reforming capacity make use of the process heat of the secondary reformer in an exchanger reformer such as *ICI's GHR* [1031] or *Kellogg's KRES* [469], [1398]. If oxygen is available, installation of a parallel autothermal reformer or a parallel *Uhde CAR unit* [472-476], (see also Section Feedstock Pretreatment and Raw Gas Production) could be considered. Description of executed revamp projects are given in [1270], [1019-1024].

Similarly, numerous modernization possibilities exist for partial oxidation plants, and they may even outnumber those for steam reforming plants. Common to both plant types is the potential for improvement of the synthesis loop and converter. Application of indirect cooling and smaller catalyst particles are frequently chosen to reduce energy consumption through lower pressure drop, reduced synthesis pressure, higher conversion, or a combination thereof. Apart from replacing existing ammonia converters, in situ modification of the internals of installed converters is a very economic approach. *Topsøe* [1011], [1026] mostly uses its Series 200 configuration; and *Ammonia Casale* [767-769], [1027], [1028], [813-816] its proprietary ACAR technology, with which more than 90 plants have been revamped so far.

With a “split-flow” configuration Kellogg proposed an in situ revamp option to change its four-bed quench converter into a two-stage intercooled converter (with two parallel beds for the second stage) using smaller catalyst particles of 1.5 – 3.5 mm and 3 – 6 mm [1293], [1294]. A promising loop modernization option for the future will be the *Kellogg KAAP process* [470], [1029], [1398].

The fact that more than 45 % of world ammonia plants are older than 30 – 35 years suggests that there is a major potential for revamp projects, even in plants which have already made modifications. Revamp histories are a constant topic at the “AIChE Annual Symposium Ammonia Plant and Related Facilities” [1350] and a wealth of information and practical experience can be found there.

A special revamping option is the integration of other processes into an ammonia plant [1318]. For example a CO production from a side stream upstream of the HT shift is possible [1356]. Hydrogen can also be produced from a side stream by using PSA. An example of coproduction of methanol is shown in Figure 78.

Figure 78. Methanol coproduction (side-stream loop)

a) Secondary reformer; b) Waste-heat boiler; c) HT shift; d) LT shift; e) Purification; f) Steam drum; g) Methanol converter; h) Catchpot; I) Syngas compressor; j) Let-down vessel

In the less integrated partial oxidation plants coproduction schemes are easier to be incorporated and there are several large installations which were directly designed to produce ammonia, methanol and hydrogen [1357], [1358].

4.8. Material Considerations for Equipment Fabrication

Hydrogen Attack. In several steps of the ammonia production process, especially in the synthesis section, the pressure shells of reaction vessels as well as the connecting pipes are in contact with hydrogen at elevated pressure and temperature with a potential risk of material deterioration [872-874].

Chemical Hydrogen Attack. Under certain conditions chemical hydrogen attack [875], [876], [878], [1408] can occur. Hydrogen diffuses into the steel and reacts with the carbon that is responsible for the strength of the material to form methane, which on account of its higher molecular volume cannot escape. The resulting pressure causes cavity growth along the grain boundaries, transforming the steel from a ductile to a brittle state. This may finally reach a point where the affected vessel or pipe ruptures, in most cases without any significant prior deformation. This phenomenon was already recognized and principally understood by BOSCH et al. [93] when they developed the first ammonia process. The resistance of steel against this sort of attack can be enhanced by alloy components which react with the carbon to form stable carbides (e.g., molybdenum, chromium, tungsten, and others). The rate of deterioration of the material depends on the pressure of the trapped methane, the creep rate of the material, and its grain structure. Areas highly susceptible to attack are those which have the greatest probability of containing unstable carbides, such as welding seams [877]. The type of carbides and their activity are strongly influenced by the quality of post-weld heat treatment (PWHT). The risk of attack may exist at quite moderate temperatures (ca. 200 °C) and a hydrogen partial pressure as low as 7 bar.

Numerous studies, experiments and careful investigations of failures have made it possible to largely prevent hydrogen attack in modern ammonia plants by proper selection of hydrogen-tolerant alloys with the appropriate content of metals that form stable alloys. Of great importance in this field was the work of NELSON [871], [878], [879], who summarized available experimental and operational experience in graphical form. These Nelson diagrams give the stability limits for various steels as a function of temperature and hydrogen partial pressure. In [880], [881], CLASS gives an extensive survey, still valid today, on this subject. Newer experience gained in industrial applications required several revisions of the original Nelson diagram. For example, 0.25 and 0.5 Mo steels are now regarded as ordinary nonalloyed steels with respect to their hydrogen resistance [875].

Physical Hydrogen Attack. A related phenomenon is physical hydrogen attack, which may happen simultaneously with chemical attack. It occurs when adsorbed molecular hydrogen dissociates at higher temperatures into atomic hydrogen, which can diffuse through the material structure. Wherever hydrogen atoms recombine to molecules in the material structure (at second-phase particles or material defects such as dislocations) internal stress becomes established within the material. The result is a progressive deterioration of the material that lowers its toughness until the affected piece of equipment cracks and ultimately ruptures.

The phenomenon is also referred to as hydrogen embrittlement. It is most likely to occur in welds that not received proper PWHT. Holding a weld and the heat-affected zone for a prolonged period at elevated temperature (an operation known as soaking) allows the majority of included hydrogen to diffuse out of the material. But this may not be sufficient if moisture was present during the original welding operation (for example if wet electrodes or hygroscopic fluxes were used), because traces of atomic hydrogen are formed by thermal decomposition of water under the intense heat of the welding procedure. Highly critical in this respect are dissimilar welds [1406], such as those between ferritic and austenitic steels [886], where the formation of martensite, which is sensitive to hydrogen attack, may increase the risk of brittle fracture.

At higher temperature and partial pressure, hydrogen is always soluble to a minor extent in construction steels. For this reason it is advisable not to cool vessels too rapidly when taking them out of service, and to hold them at atmospheric pressure for some hours at 300 °C so that the hydrogen can largely diffuse out (soaking). In contrast to the hydrogen attack described above this phenomenon is reversible.

It has been reported [882], [883] that hot-wall converters in which the pressure shell is in contact with ammonia-containing synthesis gas at 400 °C have developed cracks in circumferential welding seams to a depth nearly approaching the wall thickness in places. This was surprising because the operating conditions for the material (2.25 Cr/1 Mo) were well below the Nelson curve. One investigation [884] concluded that hydrogen attack had occurred by a special mechanism at temperatures lower than predicted by the Nelson diagram. Nitriding proceeding along microcracks could transform carbides normally stable against hydrogen into nitrides and carbonitrides to give free active carbon, which is hydrogenated to methane. High residual welding stress and internal pressure are considered to be essential for the propagation of the cracks. A rival theory [883], [885] attributes the damage to physical hydrogen attack resulting from the use of agglomerated hygroscopic flux in combination with insufficient soaking. However, for a longer time no problems were experienced for the same converter design in other cases where non-hygroscopic flux was used for welding and a more conservative vessel code was adopted, leading to less stress on account of thicker walls. But in the meantime also these converters developed cracks. So there are still questions left regarding the two theories.

Nitriding is a problem specific to the ammonia converter. It occurs in the presence of ammonia on the surface of steel at temperatures above 300 °C [888], [889-891]. With unalloyed and low-alloy steels, the nitride layer grows with time to a thickness of several millimeters. Austenitic steel, used for the converter basket, develops very thin but hard and brittle nitride layers, which tend to flake off. In the nitrided areas, the risk of formation of brittle surface cracks exists.

Temper Embrittlement. For heat-resistant steels long-term service at temperatures above 400 °C (e.g., high-pressure steam pipes) can lead to a decline in impact strength [1405]. Normally, transition temperatures (precipitous decline of notched bar impact values) of below 0 °C are encountered, but this can increase to 60 °C and more (temper embrittlement).

The susceptibility to temper embrittlement can be reduced by controlling the level of trace elements (Si, Mn, P, Sn) in steels [892], [893]. Vessels for which temper embrittlement is anticipated should not be pressurized below a certain temperature.

Metal Dusting. Metal dusting [404], [894-900] [1318], [1388] is a corrosion phenomenon which has come into focus again in the last few years with the introduction of exchanger reformer technology and the operation of steam superheaters in the hot process gas downstream of the secondary reformer waste-heat boiler. Conventional carburization is a familiar problem with high-temperature alloys in steam reforming furnaces caused by inward migration of carbon leading to formation of carbides in the metal matrix. It happens at high temperatures, typically above 800 °C, and the carbon originates from cracking of hydrocarbons. In contrast, metal dusting occurs at 500 – 800 °C on iron – nickel and iron – cobalt based alloys with gases containing carbon monoxide. The Boudouard reaction, strongly catalyzed by iron, nickel, and cobalt, is generally regarded as the source of the carbon in this case. It is assumed that thermodynamically favored sites exist for these elements at the surface and enhance the carbon deposition if the gas composition corresponds to a carbon activity >1 [898], [899].

As the name implies, the affected material disintegrates into fine metal and metal oxide particles mixed with carbon. Depending on the defects in a protective oxide film on the metal surface and the ability of the material to sustain this film, an induction period may be observed until metal dusting manifests itself as pitting or general attack. A possible mechanism was proposed by GRABKE [902] and HOCHMANN [903].

At least from a theoretical point of view, alloys formulated to form chromium, aluminum, or silicon oxide films should exhibit an increased resistance. Efforts to find solutions for this problem are continuing, but at present the following situation must be accepted: virtually all high-temperature alloys are vulnerable to metal dusting; higher steam/carbon ratios reduces this sort of corrosion; improvements may be expected by additional surface coating (for example with aluminum). With materials such as Inconel 601, 601H, 625 and similar alloys it is at least possible to reduce the attack to a level which is tolerable in practical operation. The active sites at the

metal surface which catalyze the Boudourd reaction can be poisoned by H_2S, thus inhibiting the initiation of metal dusting [899].

Hydrogen Sulfide Corrosion. Corrosion by hydrogen sulfide in partial oxidation plants can be controlled by the use of austenitic steels, but special care to ensure proper stress relief of welds is advisable to avoid stress corrosion cracking in these plants caused by traces of chlorine sometimes present in the feed oil.

Stress Corrosion Cracking. Stress corrosion cracking (SCC) of many steels in liquid ammonia is a peculiar phenomenon. It occurs at ambient temperature under pressure as well as in atmospheric storage tanks at –33 °C. Extensive studies [887], [901], [904-914] have defined the conditions under which SSC in liquid ammonia is likely to occur and how it may largely be prevented, but the mechanism is so far not fully understood. Preventive measures include maintaining a certain water content in the ammonia and excluding even traces of oxygen and carbon dioxide. Welds in pressurized vessels must be properly stress-relieved, and in atmospheric tanks it is important to select the appropriate welding electrodes, avoid excessive differences of the thickness of plates welded together and choose the correct geometry of welding seams.

[Top of Page]

5. Storage and Shipping

Producing and processing ammonia requires storage facilities to smooth out fluctuations in production and usage or shipments. If manufacture and use occur in separate locations, then appropriate transport must be arranged [1154]. This may be by ocean-going ships, river barges, rail or tank cars, or by pipeline. Ammonia is usually handled in liquid form, but in some cases delivery of ammonia vapor to downstream consumers on site may have some advantage due to savings of refrigeration energy in the ammonia plant. If there is an opportunity for on-site usage or marketing of aqueous ammonia, obtained as a byproduct of purge-gas scrubbing or, less frequently, deliberately produced, storage and handling facilities for this product will also be needed, but compared to liquid ammonia the demand is negligible.

Liquid ammonia is a liquefied gas. Its storage and distribution technologies therefore have much in common with other liquefied gases. Reference [402, vol. IV] summarizes the literature on storage, handling, and transportation of ammonia.

5.1. Storage

Three methods exist for storing liquid ammonia [1155], [1156]:

1. Pressure storage at ambient temperature in spherical or cylindrical pressure vessels having capacities up to about 1500 t
2. Atmospheric storage at – 33 °C in insulated cylindrical tanks for amounts to about 50 000 t per vessel
3. Reduced pressure storage at about 0 °C in insulated, usually spherical pressure vessels for quantities up to about 2500 t per sphere

The first two methods are preferred, and there is growing opinion that reduced-pressure storage is less attractive [402]. However, in many cases, the combination of atmospheric and pressure storage may be the most economic concept (Fig. 79). The determining factors for the type of storage — apart from the required size — are temperature and the quantity of ammonia flowing into and out of storage [1159].

Figure 79. Ammonia terminal with loading and unloading facilities

a) Sphere at ambient temperature; b) Tank at ambient pressure (refrigerated); c) Pumps; d) Compressors; e) Air-cooled condenser; f) Barge with pressure tank; g) Barge for ammonia at ambient pressure; h) Booster; i) Rail car or truck; k) Heater

Characteristic features of the three types of storage are summarized in Table 30[404]. For pressurized storage, spheres with a capacity up to 1500 t have been constructed, in which case the ratio tonnes ammonia per tonne of steel will become about 6.5.

Table 30. Characteristic features of ammonia storage tanks

Type	Typical pressure, bar	Design temperature, °C	t ammonia per t steel	Capacity, t ammonia	Refrigeration compressor
Pressure storage*	16 – 18	ambient	2.8	< 270*	none
Semi-refrigerated storage	3 – 5	ca. 0	10	450 – 2700	single stage
Low-temperature storage	1.1 – 1.2	– 33	41 – 45	4500 – 45 000	two-stage

* Refers to cylindrical tanks ("bullets"); spherical vessels see Section Pressure Storage.

5.1.1. *Pressure Storage*

This system is especially suitable for:

- Storing small quantities of ammonia
- Balancing production variations with downstream units processing pressurized ammonia
- Loading and unloading trucks, tank cars, and marine vessels carrying pressurized ammonia
- Entrance to or exit from pipeline systems

Usually, cylindrical pressure vessels are designed for about 2.5 MPa. The larger spherical vessels are designed only for about 1.6 MPa to avoid wall thicknesses above 30 mm. A coat of reflecting paint or, frequently in hot climates, an outer covering of insulation may be used on the vessels to avoid solar radiation heating. Spraying the vessel with water is very effective against intense solar radiation but does stain and damage the paint. As a rule, liquid ammonia fed to storage from a synthesis loop carries inert gases with it. Besides the prescribed safety relief valves, pressure control is provided for the storage drum by controlled bleeding of the inert gases through a pressure-reducing valve, for example, into a water wash system (Fig. 79).

Sometimes high-strength or fine-grained steels are used in making pressure vessels. These may be susceptible to stress corrosion cracking by ammonia. Safely avoiding this hazard requires careful thermal stress relief after completing all welding on the vessel.

The shape of the vessel depends above all on its capacity:

Cylindrical, usually horizontal for up to about 150 t
Spherical vessels resting on tangentially arranged support columns but also more recently, for static and safety reasons, in a suitably shaped shallow depression for about 250 – 1500 t.

Ancillary equipment, designed for at least 2.5 MPa (25 bar): meters and flow controls for pressurized ammonia feed and effluent streams; centrifugal pumps for discharging into liquid ammonia supply piping and for liquid ammonia loading; equipment for safe pressure relief for ammonia vapor and inerts (see Fig. 79 and [1156]). Design of pressure storage tanks and the related safety aspects are discussed in [1158].

Stress corrosion cracking in pressurized ammonia vessels and tanks is a problem which has been discussed in many papers [901], [904-922]. The mechanism of this phenomenon, the influence of water, and the role of oxygen are not yet completely understood, in spite of extensive research. A review is given in [923]. As it is generally accepted that addition of water may inhibit stress corrosion [402], [914], [915] it has become a widely used practice to maintain a water content of 0.2 % in transport vessels [915]. Protection may also be achieved by aluminum or zinc metal spray coating [921], [923]. More recent research [919], [923], however, has

shown that water may not give complete protection.

The prevailing opinion was that stress corrosion should not occur in atmospheric storage tanks [1162]. Therefore, it was somewhat surprising when cases of stress corrosion in atmospheric ammonia tanks were reported [925-927]. Descriptions of further incidents, inspection techniques, and repair procedures can be found in [922], [928-935], [1160].

In 1995, the capital investment, including ancillary equipment, for a 1000-t pressurized ammonia storage facility amounted to about $ 3.5 × 10^6.

5.1.2. *Low-Temperature Storage*

Modern single-train plants need to have large-volume storage facilities available to compensate for ammonia production or consumption outages. Storage equivalent to about 20 days is customary for this. Moreover, transporting large amounts of ammonia by ship or pipeline and stockpiling to balance fluctuations in the ammonia market have great importance. Therefore, correspondingly large storage facilities are necessary at ship and pipeline loading and unloading points.

For comparable large storage volumes, the capital investment costs for atmospheric pressure storage are substantially lower than for pressure storage. In spite of higher energy costs for maintaining the pressure and for feed into and out of atmospheric storage, it is still more economical than pressure storage. This applies especially to storage of ammonia coming from the synthesis loop at low temperature and loading and unloading of refrigerated ships.

For atmospheric storage at – 33 °C single tanks with a capacity up to 50 000 t of ammonia are available [1160]. Design pressure is usually 1.1 – 1.5 bar (plus the static pressure of the ammonia). The cylindrical tanks have a flat bottom and a domed roof and are completely insulated. Refrigeration is provided by recompression of the boil-off, usually with two-stage reciprocating compressors. Incoming ammonia of ambient temperature is flashed to –33 °C before entering the tank, and the vapors from the flash vessel are also fed to the refrigeration unit. Refrigeration units have at least one stand-by unit, mostly powered by a diesel engine. Single-wall and double-wall tanks are used in the industry.

Single-Wall Tanks. The single-wall tank has a single-shell designed for the full operating pressure. Mats or panels of rock wool or foamed organics (e.g., in-situ applied polyurethane foam) are used for insulation of single wall tanks. The outside insulation must be completely vapor tight to avoid icing and requires the highest standards of construction and maintenance to avoid hazardous deterioration by meteorological influences. A metal sheet covering is normally applied, and sometimes a bond wall of reinforced concrete or steel is added [1163], [1164].

Double-wall tanks are known in various designs. In the simplest version an inner tank designed for storage temperature and pressure is surrounded by a second tank. The annular space between the two walls is filled with insulation material, for example, Perlite. The main purpose of the outer shell is to contain and hold the insulation. Today's usual practice is to design the outer shell to the same standard as the inner shell. This so-called double-integrity tank concept provides an additional safety measure as the outer tank can hold the full content if the inner shell fails.

Further safety provisions include surrounding the tanks by dikes or placing them in concrete basins to contain the liquid ammonia in the event of a total failure. Discussions of such secondary containment are found in [924], [1163], [1164], [1237].

Two principle “double integrity” designs are used as shown in Figure 80. In Figure 80 A and B the inner tank has a solid steel roof and is pressure-tight, whereas the gap between inner and outer shell, which can withstand the full hydrostatic pressure at operating temperature, is only covered by the water-tight insulation. The insulation for the inner shell may fill the total annular space [e.g., lightweight concrete [1165] or Perlite (B)] or may consist of an organic foam attached to the outside of the inner shell (A).

In the design according to Figure 80 C the outer tank is pressure-tight. The inner tank has a suspended roof and the insulation fills the annular gap, which contains an atmosphere of ammonia vapor.

Because of the static loading, cellular glass or lightweight concrete [1165] is used for the floor insulation in all cold tank systems. A foundation as shown in Figure 80 A and B requires underground heating to prevent formation of a continuous ice sheet under the tank, which could lift it. If, as in Figure 80 C, the tank bottom is on piles above ground level, heating is unnecessary.

Figure 80. Arrangements of refrigerated ammonia tanks

The tanks are fabricated by welding on site, from steels which retain their notch ductility strength at low temperature. Corresponding to the decreasing static pressure, steel plate thickness in the cylindrical shell is reduced stepwise from bottom to top. Technical details and design questions are treated in [402 Vol IV], [1161], [1237], [1242], [1243]. Influence of climatic conditions on design and operation is considered in [1244]. Specific cases and foundation problems are discussed in [1239-1242]. Retrofitting of existing storage tanks is described in [1245]. Maintenance and inspection procedures are covered in [1247-1253]. For stress corrosion occurred in atmospheric tanks see Section Pressure Storage.

A rough budget figure of the capital investment in 2005 for a double-integrity tank with a capacity of 45 000 t including cooling compressors is around $ 10 × 10^6. Inclusion of facilities to receive or deliver pressurized ammonia at ambient temperature would add a few millions more. Energy consumption would also increase considerably, to about 80 kWh/t ammonia throughput. In addition, substantial investment will be necessary for a complete terminal including, for example, a jetty and equipment for ship loading and facilities for loading rail and/or tank cars.

5.1.3. *Underground Storage*

For years, the liquefied petroleum gas (LPG) industry has used pressurized underground liquefied gas storage. This technique has been applied to ammonia also. DuPont has operated a rock cavern in the United States with a capacity of 20 000 t. Norsk Hydro has one in Norway at 50 000 t. Because of the contaminants occurring in liquid ammonia stored this way and the lack of suitable construction sites, no further storage facilities of this kind have been built for a long time.

5.1.4. *Storage of Aqueous Ammonia*

To allow storage and transportation at temperatures up to 35 °C, the concentration of aqueous ammonia should not exceed 25 %, because of its vapor pressure. A small facility uses mostly cylindrical vessels. The capacity of the transporting equipment determines the storage volume, e.g., at least 40 m^3 storage volume for 30 m^3 tank cars. For larger capacities, tanks are used. If it is necessary to avoid contaminating the aqueous ammonia by iron hydroxide, austenitic (stainless) steels may be used instead of the usual carbon steels.

5.2. Transportation

Transportation in Small Containers. The most common containers are:

- Cylindrical steel bottles and pressurized flasks for about 20 – 200 kg anhydrous ammonia to meet the requirements of laboratories, small refrigeration systems, and the like
- Polyethylene canisters, metal casks, and the like for 25 % aqueous ammonia.

Transportation in Trucks and Rail Cars with Capacities Normally up to 100 m^3; Jumbo Rail Cars Holding up to 150 m^3. The most widely used methods are:

- With pressure vessels for anhydrous ammonia (maximum allowable operating pressure about 2.5 MPa)
- With atmospheric pressure vessels for 25 % aqueous ammonia
- With vessels designed for elevated pressure for high-concentration aqueous ammonia (maximum allowable operating pressure in accordance with the ammonia content up to 1.6 MPa).

A modern rail car loading station for anhydrous and aqueous ammonia is described in [1167], [1168].

The distribution in rail cars and trucks primarily serves to supply smaller processing operations and wholesale merchants. However, rail transport of liquid ammonia may to some extent supplement large marine and pipeline shipments. Reference [1169] examines rail freight cost. Normally, shipping liquid ammonia by truck is used only where other means of transport are not available, e.g., in the agricultural practice of direct fertilization.

Shipping in Ocean-Going Vessels and River Barges. Regarding the transport volume, shipping of anhydrous ammonia is far more important than transport by rail. In 2004, for example, a total of 13 × 10^6 t of anhydrous ammonia was transported by ocean-going vessels (IFA statistics). Overseas shipping gained great momentum through exports from producers in countries with low natural gas prices or low-price policies [1181]. A comparison of shipping costs is given in [1173]; for more up-to-date information consult the journal *Nitrogen* (later *Nitrogen & Methanol*, today *Nitrogen and Syngas*), published by British Sulphur, which regularly reports shipping prices. Most river barges have loading capacities of 400 to 2500 t and mostly have refrigerated load, but a few are pressure vessels. Ocean-going vessels may transport as much as 50 000 t of fully refrigerated ammonia.

Pipelines. Transport of large volumes of ammonia by pipeline [1173], [1157] over great distances is far more economical than by river barge or rail. In the USA the MidAmerica Pipeline System transports ammonia to terminals in Kansas, Nebraska, and Iowa, which are intensive agricultural areas. The Gulf Central Pipeline connects the major producers along the Texas and Louisiana Gulf coast with terminals in Iowa, Illinois, Nebraska, and Missouri. [1189]The MidAmerica Pipeline, for example, has a peak delivery capacity of 8000 t/d for a number of destinations [1170], the hold up is about 20 000 t. Maintenance is described in [1171].

As ammonia is transported at a temperature of at least 2 °C it has to be warmed up at the supplier terminal and cooled down again to – 33 °C at the receiver terminal. Exact knowledge of the $p - V - T$ properties is important [1172]. Automatic lock valves are installed at intervals of 10 miles, so that the volume which can be released between two valves is limited to 400 t.

The world's longest ammonia pipeline has been in operation since 1983 in Russia, connecting the large production facilities Togliatti/Gordlovka with the terminals Grigorowski/Odessa at the Black Sea over a distance of 2424 km [1166]. Apart from some short pipeline connections, most of them shorter than 50 km, there is no significant pipeline transport in Europe, where ammonia is predominantly further processed in downstream facilities on site and where no widespread direct application to agricultural crops exists.

[Top of Page]

6. Quality Specifications and Analysis

The quality of the ammonia product depends to some extent on the operating conditions of the production plant and storage. For example, water content from a synthesis loop receiving a dry make-up gas is about zero, whereas plants which receive the feedgas after a methanation without further drying may give a water content of 0.1 – 0.2 %. Oil may be introduced by the seal oil of the synthesis compressor, but on account of its low solubility in liquid ammonia it usually settles out on storage, so that only a minor concentration will remain in commercial deliveries. There are two commercial qualities of anhydrous ammonia: commercial (technical) grade (ammonia as received from production and storage) and refrigeration grade (technical product purified by distillation [1197] or molecular sieve adsorption). Table 31 lists the commercial specifications. The relevant standards are US Specification OA-445a, Supplement 5 (1963) and, in Germany, DIN 8960 (1972) for refrigeration-grade ammonia. To inhibit stress corrosion cracking a water content of at least 0.2 % for shipped and pipelined liquid ammonia is generally recommended and is mandatory in the USA.

Table 31. Minimum quality requirements for ammonia

Quality		Commercial grade		Refrigeration grade	
		USA	Germany	USA	Germany
Purity	wt %, min	99.5	99.5	99.98	99.98 *
Water	wt %, max	0.5	0.2	0.015	0.2
Inerts **	mL/g, max	not spec'd	not spec'd	0.1	0.08
Oil	ppm by wt	5.0	5.0	3.0	not spec'd
Free of H_2S, pyridine, and naphthene					

* Allowable boiling point change on vaporization of 5 – 97 % of the test sample, 0.9 °C

** The noncondensable gases dissolved in ammonia are H_2, N_2, CH_4, and Ar. Their amounts depend on the methods of synthesis and storage. The inerts amount to about 50 mL/kg for atmospheric storage.

Various concentrations and purities of *aqueous ammonia* are on the market. Mostly, the concentration is 25 – 30 % NH_3 and the iron content less than 10 ppm. Shipping in pressure vessels is necessary for ammonia contents above 25 % because of its elevated vapor pressure. For more stringent purity requirements for aqueous ammonia, the containers should be made of seawater-resistant aluminum (magnesium alloyed) or austenitic steels.

Analysis. Ammonia is readily detectable in air in the range of a few parts per million by its characteristic odor and alkaline reaction. Specific indicators, such as Nessler's reagent (HgI in KOH), can detect ammonia in a concentration of 1 ppm. For the quantitative determination of ammonia in air, synthesis gas, and aqueous solutions, individual (manual) and continuous (recorded) analyses can be made (for a measurement station for automatic determination of ammonium/ammonia, see [1198]). The methods used include, among others:

Acidimetry and volumetric analysis by absorption
Gas chromatography
Infrared absorption
Thermal conductivity measurement
Electrical conductivity measurement
Measurement of heat of neutralization
Density measurement (for aqueous ammonia)

Normally, the water content of liquid ammonia is determined volumetrically as the ammonia-containing residue on evaporation or gravimetrically by fully vaporizing the ammonia sample and absorbing the water on KOH.

The oil content of liquid ammonia can be tested gravimetrically by first evaporating the ammonia liquid and then concentrating the ether extract of the residue. Iron, aluminum, calcium (ammonia catalyst) and other impurities can then be determined in the ether-insoluble residue.

The inert gas content is analyzed volumetrically after the vaporized ammonia has been absorbed in water. Then the inert gas composition is analyzed chromatographically.

[Top of Page]

7. Environmental, Safety, and Health Aspects

7.1. Environmental Aspects of Ammonia Production and Handling

Measured by its overall environmental impact — air, water and soil pollution, materials and energy consumption — ammonia production is a rather clean technology, with low emissions, low energy consumption due to high-efficiency process design, and no severe cross-media dilemmas, in which improving one environmental effect worsens another. Typical emissions are given in EFMA's publication Production of Ammonia in the series “Best Available Techniques and Control in the European Fertilizer Industry” [1174].

Steam Reforming Ammonia Plants. Table 32 summarizes the emission values for steam reforming ammonia plants.

Table 32. Emissions from steam reforming ammonia plants

			Existing plants	New plants
Emission to air	NO_x (as NO_2)*	ppmv (mL/m^3)	150	75
		mg/Nm^3	300	150
		kg/t NH_3	0.9	0.45
Emission to water	NH_3/NH_4 (as N)	kg/t NH_3	0.1	0.1
Waste material**		kg/t NH_3	< 0.2	< 0.2

* At 3 % O_2.

** Spent catalysts.

The source of the NO_x emissions is the flue gas of the fired primary reformer, and in plants without a fired tubular reformer NO_x is emitted from fired heaters and auxiliary boilers, but in considerably smaller quantities. However, NO_x emissions from ammonia production, compared to the total amount from human activities, is in fact a marginal quantity. Only about 0.16 % of the anthropogenic NO_x emissions come from ammonia production. Emissions to water, generally originating from the condensate from the condensation of surplus process steam ahead of the CO_2 removal system, can largely be avoided. Minor concentrations of methanol and amines can be removed and recycled to the reformer feed by stripping with process steam, and the stripped condensate can be recycled to the boiler feed water after polishing with ion exchangers. Steam stripping without recycling to the reformer would produce a cross media effect, because in this case the pollutants would be transferred from water to air. Another possibility is use of the process condensate for feed gas saturation [458].

Partial oxidation ammonia plants have the same emission sources except for the primary reformer flue gas. The plants have an auxiliary boiler to generate steam for power production and fired heaters, which on account of the sulfur content of the fuel oil release a flue gas containing SO_2 (< 1500 mg/m^3). Other possible emissions are H_2S (< 0.3 mL/m^3), CO (30 mL/m^3) and traces of dust. The NO_x content of the flue gas depends on the configuration of the auxiliary boiler and on the extent electric power generation on the site as opposed to outside supply. The total NO_x emission per tonne of product may be somewhat lower than for steam reforming plants.

Noise. An increasing awareness has developed for noise generation and emission from ammonia plants especially in the neighborhood of residential areas [1216]. Many investigations have dealt with noise generation and noise abatement in ammonia plants [1217-1221]. The following major sources can be identified: depressurizing of large gas quantities for control or venting, steam blowing, burner noise, resonance vibrations in the flue gas ducts, and noise from compressors, blowers, and pumps. Measures for noise reduction include installing low-noise let-down valves, use of silencers, sound-reducing enclosures for compressors or housing them in closed buildings.

Emission Limits and Guideline Values for Ammonia Production. There are two categories of regulations:

1. Legally binding emission values for certain pollutants associated with ammonia production
2. Guideline values not legally binding but providing the background for requirements laid down in individual operating permits

In Europe such legally binding emission levels relevant to ammonia production exist only in Germany. In the Netherlands and Germany limits for emissions from boilers also apply for ammonia plants, for example for the reformer furnace. The present limit in Germany is 200 mg NO_x/m^3 for furnaces up to 300 MW_{th}. Specific emission guideline values are laid down in the United Kingdom. In the other European countries no national emission limits or guidelines exist; individual operation permits are negotiated, usually orientated on other cases and countries. In the United States, for example, NO_x emission level values are categorized in the Clean Air Act, which defines a significance level for the source according to the total emission (10 to 100 t/a) on the one hand, and assigns a threshold limit to the geographical area (100 t/a to 10 t/a) on the other.

For ammonia in air the authorities in Germany require that the achievable minimum level should correspond to the state of the art; originally projected values in a draft of TA Luft [1215], were not subsequently adopted; some MIK values (maximum imission concentrations) are given in VDI Richtlinie 2310 (Sept. 1974). In Germany there is no maximum ammonia concentration laid down for wastewater, it is only referred to the general interdiction to introduce poisons or harmful substances into rivers and lakes. A concentration of 1.25 mg NH_3 per liter, stated to be harmful to fish, could serve as a guideline. In the “Catalog of Water Endangering Substances” (Germany) anhydrous ammonia is not listed, but aqueous ammonia is classified in the Water Endangering Group 1 as a weakly endangering substance.

To harmonize European regulations concerning emission value permits for industrial production, the EU commission has proposed a Council Directive Concerning Integrated Pollution Prevention Control (IPPC Directive). A key element is the concept of Best Available Techniques (BAT). This directive requests an exchange between national environmental authorities, industry and nongovernmental organizations with the aim of preparing IPPC BAT Reference Documents (BREFs), which could provide a common accepted basis for emission limit value regulations of the individual EU member states. A BREF for ammonia is being prepared to serve as pilot project. A previous BAT document on ammonia was published in 1990 [1175]. For noise emissions usually local permits are negotiated, whereby in most instances the contribution to the sound level in the surrounding residential areas will be limited. For the limitation of sound levels at working places within the plant occupational safety regulations are valid which also require ear protection above a certain level. The European Fertilizer Manufacture's Associatiom (EFMA) has published a series: “Best Available Techniques for Pollution Prevention and Control in the European Fertilizer Industry” Booklet No. 1 is “Production of Ammonia” [1174]. For most up-to-date immission regulations contact the relevant authorities in the different countries.

7.2. Safety Features

In ammonia production three potential hazard events can be identified: fire/explosion hazard from the hydrocarbon feed system; fire/explosion hazard due to leaks in the synthesis gas purification, compression, or synthesis section (75 % hydrogen); and toxic hazard from release of liquid ammonia from the synthesis loop. In addition there is also a potential toxic hazard in handling and storing of liquid ammonia. The long history of ammonia production since 1913 has demonstrated this production technology is a very safe operation. Despite the complexity, size and partially severe operating conditions of vessels and piping remarkably few failures occur. It is largely thanks to such forums as the annual AIChE Safety in Ammonia Plants and Related Facilities Symposium that failures, incidents, and accidents are reported and discussed including the manner how the problems were handled and dealt with. Thus the industry as a whole has the opportunity to learn from the specific experiences of its individual members. A short desciptions of a number of accidents is found in [1371], [1397]. The severe impacts of rare events with explosions seem to be confined to a radius of around 60 m [1174]. The long industrial experience is summarized in a number of national codes and standards which have to be applied for design, material selection, fabrication, operation, and periodic technical inspections of the equipment used. This is especially important for equipment operating at high temperatures and/or pressures. Apart from proper design, skilled and well-trained operators and effective and timely maintenance are essential for safe plant operation.

General practice today is to make so-called HAZOP (hazards and operability) studies with an experienced team consisting of operating personal, process engineers (also from contractors), experts in process control and safety experts (often independent consultats from outside the company) in which, following a very meticulous procedure apparatus after apparatus is checked for potential failure and risk possibilities together with a proposal for the appropriate remedies. HAZOP studies introduced by ICI [1359-1362] for general application in chemical plants proved to be very helpful not only for existing plants but also in the planning phase of new ones. It is especially important to define and configure trip systems and trip strategies for safe plant shut downs in case of offset conditions. A similar approach, called Reliability, Availability, Maintainability (RAM) was developed by KBR [1399]. A special point is the assessment of remaining service life of equipment because many ammonia plants operate beyond there originally anticipated lifetime, which was usually defined by economic criteria [1335], [1370]. In this context the question of adequate maintenance is very important and to which extent preventive maintenance is provided. Usually single-train ammonia plants are shut down every two to five years for some weeks for changing of catalyst, equipment inspections, maintenance and, if they fit in the time schedule, also smaller revamps. The time frame of unscheduled shut downs because of problems which need urgent repairs can be used for routine maintenance operations, too. The inspections are widely carried out with nondestructive testing [1402]. Further information is given in [1350]. Statistics of plant on-stream factors, shut-down frequencies and time, as well as an investigation of the causes are found in [1400], [1407].

An area which deserves special attention with respect to safety is the storage of liquid ammonia. In contrast to some other liquefied gases (e.g., LPG, LNG), ammonia is toxic and even a short exposure to concentrations of 2500 ppm may be fatal. The explosion hazard from air/ammonia mixtures is rather low, as the flammability limits [1177-1179], [1200], [1206] of 15 – 27 % are rather narrow. The ignition temperature is 651 °C. Ammonia vapor at the boiling point of – 33 °C has vapor density of ca. 70 % of that of ambient air. However, ammonia and air, under certain conditions, can form mixtures which are denser than air, because the mixture is at lower temperature due to evaporation of ammonia. On accidental release. the resulting cloud can contain a mist of liquid ammonia, and the density of the cloud may be greater than that of air [1176], [1177]. This behavior has to be taken into account in dispersion models.

Regulations and Guidelines. For maintaining safety in ammonia storage, transfer, and handling many regulations and guidelines exist in the various countries. It is beyond the scope of this article to list them completely and to check for the most up-to-date status. It is recommanded to consult the relevant governmental authorities of the individual countries and the relevant industrial codes, applying to fabrication and operation of equipment. An overview of such regulations and standards is given in [1335].

Ammonia Spills. In an ammonia spill a portion of the liquid ammonia released flashes as ammonia vapor. This instantaneous flash is followed by a period of slow evaporation of the remaining liquid ammonia [1176], [1180]. In a release from a refrigerated tank operating slightly above atmospheric pressure, the amount of the initial flash is only a few percent of the total, whereas in a release from a pressure vessel at about 9 bar and 24 °C approximately 20 % of the spilled ammonia would flash. Figures for the proportion flashed as a function of pressure and temperature of the spilled ammonia are given in [1180]. This reference also provides quantitative information on temperature development and evaporation rate of small and large ammonia pools at certain wind velocities and also takes radiation influences (sunny or overcast sky, day or night) into account.

Spill experiments on land and on water in various dimensions have been carried out by various companies and organizations. Underwater releases were also studied. Models have been developed to mathematically describe ammonia dispersion in such events [1182-1187].

A number of real incidents with tank cars, rail cars, tanks, loading/unloading of ships and barges, and pipeline transport in which major spills occurred is described in [1222-1229], [1246], [1278] and in an excellent review on safety in ammonia storage [1188]. Training of operating personal for ammonia handling with special regard to ammonia spills is important [1208], [1214], [1246].

7.3. Health Aspects and Toxicity of Ammonia

In ammonia production, storage, and handling the main potential health hazard is the toxicity of the product itself. For this reason this section concentrates on ammonia only. Other toxic substances such as carbon monoxide or traces of nickel carbonyl (which may be formed during shut down in the methanation stage) may be only a risk in maintenance operations and need appropriate protection provisions as well as blanketing or flushing with nitrogen.

Human Exposure. The threshold of perception of ammonia varies from person to person and may also be influenced by atmospheric conditions, values as low as 0.4 – 2 mg/m^3 (0.5 – 3 ppm) are reported in [1190], but 50 ppm may easily detected by everybody [1304]. Surveys [1191] found concentrations from 9 – 45 ppm in various plant areas. Though initially irritated, exposed persons may quickly become accustomed to these concentrations. Another report [1192] gives concentration limits for short time exposures as follows: 100 ppm (10 min); 75 ppm (30 min) 50 ppm (60 min). The time-weighted average Threshhold Limit Value (TLV) of the ACGIH is 25 ppm (or 18 mg/m^3) [1193]. This recommendation was supplemented by a value for short-time exposure: 35 ppm for 15 min. The MAK value is 50 ppm.

Exposure to higher ammonia concentration has the following effects: 50 – 72 ppm does not disturb respiration significantly [1305]; 100 ppm irritates the nose and throat and causes a burning sensation in the eyes and tachypnoe [1305]; 200 ppm will cause headache and nausea, in addition to the above symptoms [1306]; at 250 – 500 ppm tachypnoe and tachycardia [1306]; at 700 ppm, immediate onset of burning sensations in the eyes [1307]; 1000 ppm causes immediate coughing [1308]. The symptomatology of various exposure levels is also described in [1193-1195]. At 1700 ppm coughing with labored breathing, sometimes with momentary inability to breath (coughing of rescued persons may continue for hours). 2500 to 4500 ppm may be fatal after short exposure; 5000 ppm and higher causes death by respiratory arrest [1188].

The metabolism seems not to be significantly changed after exposure to 800 ppm [1308]. A discussion of metabolism and of acute and chronic health problems caused by ammonia can be found in [1196].

Toxicology. Ammonia is a strong local irritant. On mucous membranes alkaline ammonium hydroxide is formed, which dissolves cellular proteins and causes severe necrosis (corrosive effect).

The primary target organ is the pulmonary system, and the following symptoms can be observed: pharyngitis, laryngitis, tracheobronchitis, nausea, vomiting, increased salivation, reflectoric bradycardia, and life-threatening symptoms, such as edema of the glottis, laryngospasm, bronchospasm, and interstitial lung edema [1283].

Ammonia or ammonium hydroxide can penetrate the cornea rapidly, leading to keratitis, damage of the iris, cataract, and glaucoma [1284].

Oral ingestion of aqueous ammonia can corrode the mucous membranes of the oral cavity, pharynx, and esophagus and cause the shock syndrome, toxic hepatitis, and nephritis. Because of its corrosive action constrictions of the esophagus may result.

Ammonia is absorbed rapidly by the wet membranes of body surfaces as ammonium hydroxide, converted to urea, and excreted by the kidneys [1285]. The capacity of detoxification via urea is sufficient to eliminate the ammonium ion when ammonia is inhaled in nonirritating concentrations. The inhaled ammonia is partly neutralized by carbon dioxide present in the alveoli [1286]. Only a small fraction of the ammonia is exhaled unchanged by the lungs (12.3 % at an inhalation concentration of 230 ppm) [1287]. Repeated inhalation can cause a higher tolerance because the mucous membranes become increasingly resistant [1300]. Additional information on the toxicology of ammonia can be found in [1288-1292], [1295-1299], [1309-1315].

Carcinogenicity. Ammonia failed to produce an increase in the incidence of tumors in Sprague Dawley rats even when the protein ratio in the diet was increased or when urea was added [1301].

Lifetime ingestion of ammonium hydroxide in drinking water by mice was without any carcinogenic effects [1302].

Mutagenicity. Ammonia is not mutagenic in the Ames *Salmonella* system and in *Saccharomyces cerevisiae* [1303].

[Top of Page]

8. Uses

In 2003 about 83 % [1238] of ammonia production was consumed for fertilizers. Ammonia is either converted into solid fertilizers (urea; ammonium nitrate, phosphate, sulfate) or directly applied to arable soil.

The industrial use of ammonia is around 17 % [1238]. Actually every nitrogen atom in industrially produced chemicals compounds comes directly or indirectly from ammonia. An important use of the ammonia nitrogen, partly after conversion to nitric acid, is the production of plastics and fibers, such as polyamides, urea – formaldehyde – phenol resins, melamine-based resins, polyurethanes, and polyacrylonitrile. Another application is the manufacture of explosives, hydrazine, amines, amides, nitriles and other organic nitrogen compounds, which serve as intermediates for dyes and pharmaceuticals. Major inorganic products are nitric acid, sodium nitrate, sodium cyanide, ammonium chloride, and ammonium bicarbonate. Urea production consumed about 40 % of the ammonia produced in 1995.

In the environmental sector ammonia is used in various processes for removing SO_2 from flue gases of fossil-fuel power plants. The resulting ammonium sulfate is sold as fertilizer. In the selective catalytic reduction process (SCR) the NO_x in flue gases is reduced in a catalytic reaction of the nitrogen oxides with a stoichiometric amount of ammonia [1233-1236]. Also noncatalytic reduction is applied with ammonia or urea solutions.

Ammonia may also serve as a solvent in certain processes. Another application is the nitriding of steel. An old and still flourishing business is the use of ammonia as refrigerant, based on its low boiling point and its high heat of evaporation. For some time heavy competition came from chlorofluorocarbons (CFCs), but with increasing environmental concern regarding the application of CFCs ammonia's position is strengthening again. Ammonia is applied in a large number of industrial and commercial refrigeration units and air-conditioning installations [1-4]. In addition to the high specific refrigeration effect, the ammonia has the following advantages: it is noncorrosive; it tolerates moisture, dirt, and oil contaminants; it is cheap and there are many suppliers. A drawback is its toxicity.

The production of smaller volumes of hydrogen/nitrogen mixtures used as protective gases for chemical products [5] and for metal-working processes [6] by

decomposition of ammonia over iron- or nickel-based catalysts at 800 – 900 °C may be an economic alternative where production or purchase of pure hydrogen is too expensive (see also ⟶ Hydrogen – Hydrogen from Ammonia), [1199]. Energy-related applications of ammonia are proposed in [1235].

[Top of Page]

9. Economic Aspects

About 1.4 % of the world consumption of fossil energy (not including combustion of wood) goes into the production of ammonia. In developing countries, ammonia is generally one of the first products of industrialization. As 83 % of world nitrogen consumption is for fertilizers it might be expected that ammonia production should develop approximately in proportion to the growth of world population. This was roughly the case in the mid-1980s as can be seen from Figure 81 [406]; since then the rate of increase in production has been markedly slower than that of world population. This has been mainly for economic reasons in developing countries and for ecological reasons in industrialized countries.

Figure 81. Development of ammonia production and world population

The political changes in the former Eastern Bloc caused a dramatic slump in 1991 – 1993. Table 33 shows the development from 1985 to 2006. Because of the surplus of capacity over demand from the mid-1980s to the mid-1990s the tendency to invest in new plants was rather small and revamping measures aiming at energy saving dominated. A retarding effect resulted also from the financial crises in Asia in the early 1990s associated with a retreat from goverment subsidizing.

Table 33. World ammonia supply/demand balance (10^6 t/a ammonia) [1201-1203, 1207], [1363-1365]

Year	1985	1990	1991	1992	1993	1994	1995	1998	2000	2001	2003	2004	2005	2006
Capacity	143.9	148,7	148.8	151.2	153.9	141.7	142.7	147.6	151.1	151.1	163.2	165.5	168.3	175.0
Demand	111.7	114.6	119.2	113.1	109.7	113,4	115.6	126.7	129.8	126.0	132.3	142.4	142.2	146.5
Capacity utilization, %	77.7	77.1	80.1	74.8	71.3	80.0	81.0	85.9	85.9	8.34	81.07	86.0	84.5	83.7

From 2002/2003 onwards new ammonia projects materialized in increasing capacity numbers (see Fig. 82). The required plant availabilities to satisfiy the expected demand are between 80 and 85 %. However, since the industry is capable to reach plant availabilities of 91 – 93 %, around 40 000 t/d of capacity is idle now. Much of this idle capacity is in the United States (because of the extreme increase of the natural gas price) and in Eastern Europe. The shift is to plants in areas with low gas cost (Middle East, Trinidad, Venezuela).

The future growth of the nitrogen demand supplied by synthetic ammonia is expected to be larger than the growth of the global population. Economic growth with the tendency of higher meat consumption and improvement of nutrition in developing countries are driving forces for increased fertilizer production. Meat consumption is presently increasing with around 3 % per year [1238], the nitrogen required to produce the animal feed is in the range of 20 – 30 % of the total nitrogen demand for fertilizers. The nonfertilizer use of nitrogen is governed by the general economic development and by environmental legislation [1365].

Figure 82. World ammonia capacity and demand

The geographical distribution of world ammonia capacity is shown in Figure 83. Europe and North America, which now together have a 26 % capacity share, lost their leading position (54 % in 1969) to Asia, which now accounts for 46 % (17 % in 1969), as may be seen from Figure 83.

Figure 83. Geographical distribution of world ammonia capacity [1364]

Acccording to the figures for 2002 [1366], the P. R. China is the largest producer with 36.6 × 10^6 t/a NH_3, followed by North America (USA and Canada) with 16.6 × 10^6 t/a, the FSU countries with 15.9 × 10^6 t/a, India 11.9 × 10^6 t/a and Western Europe 11.4 × 10^6 t/a.

Because of the steadily increasing natural gas prices in the United States and Western Europe ammonia imports from low-gas-price locations are constantly growing and a number of ammonia plants have been temporarily or permanently closed.

The major importers of ammonia are Western Europe (2002: 3.7 × 10^6 t) and the United States (2002: 5.6 × 10^6 t), whereas, on account of their enormous natural gas reserves, the FSU countries (4.5 × 10^6 t), Trinidad (3.5 × 10^6 t) and the countries in the Middle East, whose producers export predominantly to Asia, are dominant in ammonia export. Nearly three-quarters of world natural gas reserves (2003) are concentrated in two areas: in the former Soviet Union (32 %) and the Arabian Gulf (41 % including Iran). Iran, which owns 15 % of the world gas reserves, is so far not a major ammonia producer and not an ammonia exporter. An indication of the natural gas prices is given in Table 34.

Table 34. Natural gas prices at different locations around 2004 [1365], [1367], [1368]

Location	$/$10^6$ Btu*
USA	> 6.00
Canada	4.8
Western Europe	4.4
Trinidad	1.6
Venezuela	0.75
Argentina	1.25
Russia	0.9

*1 Btu (British thermal unit) = 1055 J.

For for comparative production cost evaluations these figures should be taken with some care, because they are statistically compiled and might not always be suited for an individual case or a concrete situation. In 2005 gas prices dramatically increased in the USA, where they reached in some areas values above \$ 9/10^6 Btu, and also in Europe the \$ 5 line was crossed.

The feedstock question is discussed in [1204]. Natural gas is by far the most economical feedstock for ammonia production, achieving the lowest energy consumption and requiring the lowest investment. This can be seen from Table 35, which compares ammonia production costs in North-West Europe for different feedstocks using today's best technological standards for each process.

Table 35. Ammonia production costs from various feedstocks (2004)[a]

Feedstock (Process)	Natural gas(steam reforming)	Vacuum residue (partial oxidation)	Coal(partial oxidation)
Feedstock price, \$/10^6 Btu[b] (LHV)	4.6*	2.7*	2.5*
Consumption, 10^6 Btu[b] per tonne NH_3	27	36	45
Feed + energy (fuel), \$ per tonne NH_3	124.2	97.2	112.5
Other cash costs, \$ per tonne NH_3	38.0	51.0	75.0
Total cash costs, \$ per tonne NH_3	162.2	148.2	187.5
Capital related costs[c], \$ per tonne NH_3	65.1	96.3	162,8
Total production costs, \$ per tonne NH_3	227.3	243.5	350.3
Investment[c], 10^6 \$	250	370	625

[a]The 2004 Feedstock prices are taken from the BP Statistical Review of World Energy 2005 [1205]. The price of the vaccuum residue is the heavy fuel oil price minus a deduction of \$ 50/t [1369].
[b]1 Btu (British thermal unit) = 1055 J.
[c]The investment for steam reforming is a budget figure based on recent estimates for a 2000 t/d plant inside battery limits and excludes any offsites, a 45 000 t ammonia tank with refrigeration is included. It is assumed that the utilities are supplied at battery limit in required specification. Investment figures for the vacuum residue and coal-based plants are derived from the steam reforming figure by the well-known investment relation factors. Capital related costs depend highly on the financing condition and on ROI (return on investment) objectives of the investor. So the figures for the capital related costs in the table assuming debt/equity ratio 60:40, depreciation 6%, 8 % interest on debts, 16 % ROI on equity, are only an example to illustrate this substantial contribution to the total costs.

Consumption figures for older plants can be considerably higher than those for modern ones as used in Table 35., so that the world-wide average figure for steam reforming plants is probably between 31 and 33 10^6 Btu per tonne NH_3. For the annual production 330 days of operation per year were assumed. For a specific plant the on-stream factor might be lower for market reasons or because of outages due to technical problems, which will increase the fixed costs per tonne.

With natural gas prices above \$ 9/10^6 Btu in the USA coal-based production would be competitive at full production costs [1411]. But the relative high investment cost for the coal-based plants create more difficulties for the project financing. Nevertheles there are already feasibility studies made in the USA for coal-based production using Illinois coal (\$ 30/t, \$ 1.30/10^6 Btu) [1372]. For coal as an alternative to natural gas see also [1374].

The total investment for a new ammonia production can vary considerably depending on the location and its specific conditions. In the example of Table 35. an industralized site is assumed where all the necessary off-site installations are already existing. For a remote site with heavy forest vegetation where all neccessary offsite facilities like workshops, fire fighting, ambulance, administration, and a few housing buildings and roads have to be included, the total investment for a 2000 t/d capacity could easily reach \$ 450 for a natural gas steam reforming plant.

A special case is the P. R. China where as a consequence of its large coal reserves and limited gas and oil reserves more than 60 % of the ammonia production uses coal, 20 % uses natural gas and the rest is oil-based [1370]. In the rest of the world 90 % of the ammonia production uses natural gas. For the future coal has prospects [1411, 1412] as can be seen from world reserves of fossil energy and their present consumption rate (Table 36).

Table 36. World reserves and consumption rate of fossil feestocks in 2004 [1368]

	Coal, t	Oil, t	Natural gas, Nm^3
Reserves	456×10^9	162×10^9	180×10^{12}
Consumption per year	2778×10^6	3868×10^6	2692×10^9
Years of expected supply	164	42	67

Only about 14 % of the ammonia is traded as such. Only for this proportion prices are regularly published in *Nitrogen + Syngas*, FINDS, by Ferticon, Green Market, IFA, EFMA, TFI statistics and other publications. Apart from some direct uses (3%) all ammonia is converteted into downstream products (Fig. 84).

Figure 84. Applications of ammonia

UAN = Urea – ammonium nitrate; DAP = Diammonium phosphate; MAP = Magnesium – ammonium phosphate

Even with inclusion of the shipping costs from the low-gas-price areas Trinidad (\$ 25/t) and from Russia/Ukraine (\$ 65-70 /t) to the US Gulf Coast these imports can easily compete with the domestic production as to be seen from Table 37.

Table 37. Ammonia cash costs 2005[*]

	USA	Trinidad	Russia	Arabian Gulf
Nat. gas price \$/10^6 Btu	9 – 10	1.6 – 2.0	0.9	0.5 – 1.0
Feedstock costs, \$ per tonne NH_3	310	50	30	16 – 31
Other costs, \$ per tonne NH_3	30	30	30	30
Freight, \$ per tonne NH_3	-	25 [1370] to USA	70 [1370] to USA	25 – 70 to Asia
Cash costs, \$ per tonne NH_3	309 – 340	105 – 155	130	71 – 131

*For simplicity reasons equal gas consumption and other costs are assumed.

Because of the economy of scale there is the tendency to choose a capacity of 2000 – 2200 t/d for new projects at low-gas-price locations and some investors are looking for even larger sizes. The largest single stream plant with 3300 t/d was built by Uhde in Saudi Arabia and started up in 2006. Technical feasability studies for 5000 t/d plants are made by various contractors (see Section Single-train Capacity Limitations – Mega-Ammonia Plants). But besides technical feasability there are questions about the economic risk and financing.

[Top of Page]

10. Future Perspectives

It is difficult to venture a prognosis for the future development of ammonia production technology. As about 85-87 % of the ammonia consumption goes into the manufacture of fertilizers, it is obvious that the future of the ammonia industry is very closely bound up with future fertilizer needs and the pattern of the world supply.

Nitrate pollution, which may become a problem in some countries, is sometimes used as an argument against the use of industrially produced “inorganic” or “synthetic” fertilizers and in favor of more “organic” or “natural” fertilizers. But this is a misconception, because degradation of biomass and manure also leads to nitrate run-off. In addition, the amount of this biological material is far to small to supply the increasing demand of the agriculture necessary to feed the growing world population. The solution to the run-off problem therefore can also not consist in cutting back fertilizer application, which would be disastrous in developing countries, but is likely to lie in a better management of the timing of fertilizer application, requiring a better understanding of the biological nitrogen cycle. Estimates of fixed nitrogen from natural sources and antropogenic activities on global basis are found in [1138-1142].

A fundamental question is, whether there are other options for the future than the present ammonia technology, which involves severe temperatures and pressures. The research for new approaches should strive for the following, admittedly rather ambitious and idealized objectives: ambient reaction conditions, less or no consumption of fossil energy, lower investment, simple application, even in remote developing areas, and wide capacity range. As the major demand is in agriculture, biological processes for in vivo conversion of molecular nitrogen into fixed nitrogen would probably be the first choice. Alternatively abiotic processes (in vitro) with homogeneous catalysis under mild reaction conditions could be discussed for ammonia production.

Biological Processes. Certain bacteria and blue-green algae are able to absorb atmospheric nitrogen, by themselves or in symbiosis with a host plant, and transform it into organic nitrogen compounds via intermediate ammonium ions, whereby the host plant indirectly supplies the large amount of energy needed. A well known example is the symbiotic relationship between legumes (e.g., peas, beans, soybeans, lupins) and Rhizobium bacteria, which settle in their root nodules. Ammonia synthesis is performed by the enzyme nitrogenase [1147-1149]. For the synthesis of the nitrogenase in the cell the so-called NIF gene is responsible. Apart from Rhizobium bacteria a number of other organisms have nitrogen fixation potential, living in symbiosis or providing the required energy from their own metabolism. Genetic engineering to extend biological nitrogen fixation to other plant groups pursues various routes [1150, 1151]:

1. Modifying Rhizobium to broaden its spectrum of host plants
2. Transferring the NIF gene to other bacteria which have a broader spectrum of host plants but have no natural nitrogen-fixing capability
3. Engineering soil bacteria to absorb and convert nitrogen to ammonia and release it to the soil [1143]
4. Inserting the NIF gene directly into plants

Especially the last option, to design nitrogen-fixing species of traditional crops such as wheat, rice, and corn, leads to the following questions: Would it be preferable to fix nitrogen in the leaves where energy is available or in the roots, to which carbohydrates have to be transported? If fixation is performed in the leaves, then how can the problem of the proximity of oxygen generated in the photosynthesis and oxygen-sensitive nitrogenase be dealt with? To what extent will the energy required by a plant to fix nitrogen affect overall productivity?

The last question has been discussed in some detail [1209]. For the conversion of molecular nitrogen into ammonia the following stoichiometric equation may be formulated:

$$0.5\,N_2 + 1.5\,H_2O \rightarrow NH_3 + 0.75\,O_2$$

$$\Delta F^0_{298} = +340\,\mathrm{kJ/mol}\,,\ \ \Delta H^0_{298} = +383\,\mathrm{kJ/mol}$$

The oxidation of glucose generates 3140 kJ/mol and with 100 % efficiency only about 0.11 mol of glucose would be required to produce one mole of ammonia. This ideal can, of course, never be achieved. In the molybdenum-containing nitrogenase a transfer of eight electrons is involved in one catalytic cycle:

$$N_2 + 8\,H^+ + 8\,e^- \rightarrow 2\,NH_3 + H_2$$

As seen from this equation two electrons are “wasted” in forming molecular hydrogen, which also seems to be unavoidable in vivo. This stoichiometry suggests an efficiency of 75 %, but if additional functions associated with fixation are taken into account, a maximum overall efficiency of 10 – 15 % is estimated for the enzyme, and even less for the bacteria as a whole [1210]. In investigations on Rizobium [1211], [1212] it was shown for the nodulated roots of peas that 12 g of glucose are consumed to produce 1 g of fixed nitrogen. Using this efficiency for the case where all the fixed nitrogen in the plant is supplied only via this route, a yield loss of 18 % would result. Nitrate, for example from a fertilizer, absorbed by the plant is transformed to ammonia involving a free energy change $\Delta F^0_{298} = +331$, which is comparable to the free energy change for converting molecular nitrogen to ammonia, as shown in the stoichiometric equation above.

This is a somewhat surprising result, which suggests that nitrogen supply with nitrate has an energetic advantage over the biological fixation process [1213]. A definite answer to this question will only be possible when genetically engineered nitrogen-fixing plants are available in sufficient amounts for field tests. There is no doubt that some day in the future genetic engineering will succeed in designing nitrogen-fixing plants for agricultural crops.

But until this will become a reality, application of selected natural nitrogen-fixing microorganisms to crops would be an intermediate solution to reduce industrial fertilizer consumption. In the United States field tests with *Azospirillium* applied to corn could demonstrate a considerable increase in harvest yield [1151]. Careful directed application of blue-green algae, (*Anabaena azolla*) and water fern (*Azolla pinata*) in tropical rice fields is also very promising [1152, 1153]. Unlike most diazotropic bacteria, blue-green algae are self-sufficient in that they themselves produce the energy necessary for the nitrogen fixation by photosynthesis.

Abiotic Processes [1209]. Possibilities of converting molecular nitrogen into ammonia in homogeneous solution by using organometallic complexes have been studied from around 1966 onwards. Numerous investigations resulted in the laboratory-scale synthesis of ammonia , but with rather low yields. The prospects of this route are not judged to be very promising in terms of energy consumption and with respect to the costs of the rather sophisticated catalyst systems. Photochemical methods [1144], [1145], [1146], to produce ammonia at ambient temperature and atmospheric pressure conditions in presence of a catalysts have up to now attained ammonia yields which are far too low to be economically attractive. For a detailed review of biological and abiotic nitrogen fixation, see ⟶ Nitrogen Fixation and [1209]; additional literature references can be found in [1140], [1141], [1142], [1147], [1148].

Conclusions. Based on the foregoing discussion and the evaluation of present technology (see also [406]) and research efforts one may formulate the scenario for the future development of ammonia production as follows:

1. For the major part, ammonia production in the next 15 to 20 years will rely on the classic ammonia synthesis reaction combining nitrogen and hydrogen using a catalyst at elevated temperature and pressure in a recycle process.
2. It is very likely that genetic engineering will succeed in modifying some classical crops for biological nitrogen fixation and that large-scale application will occur predominantly in areas with strongly growing populations to secure the increasing food demand. This development may be pushed by the fact that compared to the classical fertilizer route less capital and less energy would be needed. This might happen in the future but an estimate regarding extent and time horizon is difficult. But even with the introduction of this new approach, traditional ammonia synthesis will continue to operate in parallel, because it might be necessary to supplement the biological nitrogen fixation with classical fertilizers. In addition, the existing ammonia plants represent a considerable capital investment and a great number of them may reliably operate for at least another 20 to 30 years from a mere technical point of view.
3. Natural gas will remain the preferred feedstock of present ammonia production technology in the medium term (15 – 20 years) as may be assumed from the world energy balance shown in Table 26. Partial oxidation of heavy hydrocarbon residues will be limited to special cases, but coal gasification could have a renaissance within this period.
4. Technical ammonia production based on non-fossil resources, e.g. electrolysis (power from nuclear, solar, water or geothermic energy) or gasification of biomass in this time frame will play no role.

5. Ammonia technology will not change fundamentally, at least not in the next 10 to 15 years. Even if there are radical, unforeseeable developments, they will need some time to mature to commercial applicability. With the traditional concepts, the margins for additional improvements have become rather small after years of continuous research and development. Thus further progress may be confined to minor improvements of individual process steps, catalysts and equipment design.
6. The best energy figure so far achieved in commercial production is around 28 GJ per tonne NH_3. With the ruthenium-based catalysts M.W. Kellogg claims a figure of 27.2 GJ per tonne NH_3. Further reduction would need an even more active catalyst to operate at a much lower synthesis pressure, for example, at around 30 bar, which is the usual pressure level of steam reforming. The probability of finding such a catalyst is rather small after all the years of intensive research. Figures between 27 and 28 GJ per tonne NH_3 already correspond to a rather high efficiency of around 75 % with respect to the theoretical minimum of 20.9 GJ per tonne NH_3 (calculated as stoichiometric methane demand, see Section Minimum Energy Requirement for Steam Reforming Processes).
7. The bulk of ammonia production in the near future will still be produced in world-scale plants of capacity 1000 – 2000 t NH_3 per day. Small capacities will be limited to locations where special logistical, financial or feedstock conditions favor them. More plants in high-gas-cost areas will be closed and the gap will be filled by higher imports from low-price gas areas, where new plants, intended for export, probably also mega-plants, will be built.
8. Most newer technology developments will mainly reduce investment costs and increase operational reliability. Smaller integrated process units, such as exchanger reformers in various configurations, contribute to this reduction and will achieve additional savings by simplifying piping and instrumentation. Progress in instrumentation and computer control could reduce the effective overall energy consumption achieved over the course of a year by tuning plants continuously to optimal operating conditions.

1. Ammonium Nitrate

Ammonium nitrate [*6484-52-2*], NH_4NO_3, is a major chemical product. It is produced most frequently by neutralization of nitric acid with ammonia and is mainly processed into high-quality fertilizers. As a straight fertilizer, it accounts for 24 % of world consumption of nitrogen fertilizers and, in addition, is present in many blended and complex fertilizers, thus making an important contribution to feeding the world's population. Ammonium nitrate is also used as an oxidizing agent and a constituent of many explosives.

1.1. Physical and Chemical Properties

Ammonium nitrate is a colorless salt, M_r 80.05, d_4^{20} 1.725, specific heat capacity 1.70 J g^{-1} K^{-1} between 0 and 31 °C; *mp* 169.6 – 170 °C. The reaction forming ammonium nitrate from ammonia and nitric acid is highly exothermic:

$$NH_3\,(g) + HNO_3\,(l) \longrightarrow NH_4NO_3\,(s) \quad \Delta H = -146\,\text{kJ/mol}$$

The salt has five modifications:

I	169.6	to	125.2 °C	cubic
II	125.2	to	84.2 °C	tetragonal
III	84.2	to	32.3 °C	orthorhombic
IV	32.3	to	– 16.9 °C	orthorhombic
V	below		– 16.9 °C	tetragonal

The transition at 32.3 °C is of particular significance for storage of fertilizers containing ammonium nitrate: on passing through the transition repeatedly, the fertilizer granules lose strength and finally disintegrate because of the differing densities.

Ammonium nitrate dissolves readily in water; in addition, the salt is hygroscopic. Therefore, care must be taken to avoid moisture during transport and storage. When the salt dissolves in water, heat is absorbed; therefore, ammonium nitrate can be used in freezing mixtures, for example, in mixtures with sodium chloride and ice. The heat of solution in an almost infinite quantity of water is + 26.4 kJ/mol at 18 °C, the integral heat of solution to saturation is + 16.75 kJ/mol, and the heat of solution in saturated solution is + 15 kJ/mol. The physical properties of ammonium nitrate solutions important for concentration by evaporation on an industrial scale are shown in Tables 1, 2, and 3 and Figures 1 and 2 (see below, and next page).

Figure 1. The system $NH_4NO_3 - H_2O$
Roman numerals denote the modifications

The solubility of ammonium nitrate in some nonaqueous solvents is considerable. The salt dissolves in liquid NH_3 and vigorously absorbs NH_3 to form solutions known as Divers liquid. Aqueous ammonium nitrate solutions 50 – 70 % by weight vigorously absorb NH_3 and may be used for stripping NH_3 from gases. Solutions such as these are also used for ammoniating superphosphate. The salt dissolves in methanol to give solutions of about 20 % at 30 °C and about 40 % at 60 °C. Its solubility in ethanol is about

64	204.0	2.552

4 % at 20 °C and is minimal in acetone. Ammonium nitrate is insoluble in ether.

Ammonium nitrate is a powerful oxidizing agent. It is stable at normal temperature and pressure. On heating, it decomposes above 170 °C to gases. These reactions are promoted especially by small quantities of chlorine or free acid.

1.2. Production

Ammonium nitrate is produced mainly from ammonia and nitric acid. Ammonium nitrate is also formed in the production of nitrogen – phosphorus (NP) and nitrogen – phosphorus – potassium (NPK) fertilizers on decomposition of crude phosphate with nitric acid, the salt generally remaining in the fertilizers. In Europe the reaction of calcium nitrate with NH_3 and CO_2 is also used to produce NH_4NO_3.

1.2.1. From Ammonia and Nitric Acid

The neutralization of 45 – 65 % HNO_3 with gaseous NH_3 is accompanied by the release of 100 – 115 J per mole of NH_4NO_3 [6]. In most processes this considerable heat of reaction is used for partial or complete evaporation of the water. Depending on the pressure and the concentration of the nitric acid, 95 – 97 % solutions of ammonium nitrate can be obtained. During neutralization, the components must be mixed quickly and thoroughly in the reactor to avoid local overheating, losses of nitrogen, and decomposition of the ammonium nitrate.

One design of a neutralization reactor is shown in Figure 3 [7]. Ammonia and acid enter the inner tube, the actual neutralization zone, through pipes a and b. The neutralizer is filled to

Figure 4. The UCB process
a) Reactor; b) Scrubber; c) Falling film evaporator

mark A with ammonium nitrate solution. While the solution boils vigorously in the outer compartment f, boiling is suppressed in the inner compartment e because of a slight excess pressure. The higher the temperature in the neutralizer (to 180 °C in pressure processes), the more important it is to maintain an exact pH value and to avoid introducing chlorides, heavy metals, and organic compounds. In addition, the quantity of ammonium nitrate at elevated temperature is kept as small as possible. The neutralizers and evaporators are generally constructed from Cr – Ni stainless steels.

A reduced-pressure process is operated by Chemico [6]. Normal-pressure installations use the Uhde process [8], the SBA (Soc. Belge de l'Azote) process [9], etc.; they and are characterized by low reaction temperatures and minimal corrosion. The heat can be best utilized if neutralization is carried out under pressure [10]. Steam can be generated in some processes. Operation under pressure goes back to FAUSER [11]. The pressure processes differ in removal of the heat of reaction.

In the *UCB process* (Fig. 4) [12], a heat exchanger in the pressure reactor uses a part of the heat of reaction to make steam.

Ammonia and 52 – 63 % HNO_3 are preheated and sprayed into the sump of the reactor. The pressure in the reactor is approximately 0.45 MPa (4.5 bar), the temperature is 170 – 180 °C, and the pH is 3 – 5. The pH is kept in this range by controlling the ratio of reactants. The heat exchanger cools the reaction mixture, and neutralization follows a stable course. The 75 – 80 % NH_4NO_3 solution leaving the reactor is concentrated to 95 % by evaporation in a falling film evaporator. The heat of reaction generates

1) process steam out of the evaporating water from the nitric acid. This is used in the process to preheat boiler feed water and nitric acid and to operate the falling film evaporator.
2) pure steam up to 0.55 MPa (5.5 bar) in the heat exchanger. This can be fed into the steam pool and used for other purposes.

The pH 3 – 5 reduces nitrogen losses into the process steam. The working conditions are adjusted

Figure 5. The Stamicarbon process

so that excess process steam does not accumulate.

Another process that works under pressure is the *Stamicarbon process* (Fig. 5) [13]. The neutralizer is a loop reactor that opens into a separator. The reaction solution is circulated without a pump by heat generated.

Nitric acid (60 wt%), preheated ammonia, and a small quantity of sulfuric acid are introduced at the lower end of the loop. The reactor operates at 0.4 MPa (4 bar) and 178 °C. The ammonium nitrate solution formed in the reactor has a concentration of 78 %. The steam removed at the top of the separator is passed through a mist eliminator and is mainly used to concentrate the NH_4NO_3 solution to 95 % in a vacuum evaporator. Excess steam is condensed, and ammonia is recovered from the condensate and returned to the reactor. In a second evaporator, the concentration can be increased to 98 – 99.5 % using fresh steam. The temperature of the ammonium nitrate solution is kept below 180 °C throughout neutralization and evaporation.

The *NSM/Norsk Hydro pressure process* (Fig. 6) [14] uses preheated ammonia and nitric acid.

The pressure in the reactor is between 0.4 and 0.5 MPa (about 4.5 bar), and the temperature ranges from 170 to 180 °C, conditions corresponding to a 70 – 80 % solution. Forced circulation and a thermal siphon effect circulate the solution through the reactor. Some of the heat of reaction is used to generate pure steam in an external boiler; some vaporizes water in the reactor, producing process steam, which is used to concentrate the ammonium nitrate solution to 95 %. The ammonia losses are kept small by washing the process steam with nitric acid, which is added to a circulating ammonium nitrate solution. Further concentration of the NH_4NO_3 solution, to 99.5 %, is carried out with steam in a special vacuum evaporator.

Figure 6. NSM/Norsk Hydro process
a) Ammonia evaporator/superheater; b) Nitric acid preheater; c) Boiler; d) Reactor; e) Reactor separator; f) Scrubber; g) Flash-tank; h) Evaporator; i) Separator; k) Condenser; l) Ejector; m) Tank

In the United States the *Stengel process* is significant [15], [16]. It produces anhydrous ammonium nitrate directly.

The ammonia and the ca. 58 % nitric acid are preheated with fresh steam and fed into a packed vertical tube reactor at 0.35 MPa (3.5 bar) and 240 °C. The mixture of NH_4NO_3 and steam is expanded into a vacuum in a centrifugal separator. After stripping with hot air, a 99.8 % NH_4NO_3 melt is discharged, onto a cooled steel belt, solidified, and then broken up or granulated. The steam is removed at the top.

In all these processes the maintenance of the desired pH is most important. Where the reaction temperatures are below 170 °C, the pH is kept between 2.4 and 4 to minimize nitrogen losses. In pressure neutralizers, a higher pH, 4.6 to 5.4, is necessary on account of the higher temperatures and greater danger of decomposition.

1.2.2. Conversion of Calcium Nitrate Tetrahydrate

The production of nitrophosphate fertilizers by digestion of crude phosphate with nitric acid in the Odda process produces as a byproduct calcium nitrate tetrahydrate, $Ca(NO_3)_2 \cdot 4\,H_2O$, in considerable quantities (→ Fertilizers). The output of nitrophosphates is increasing, while demand for calcium nitrate is declining. In a process introduced some years ago, the calcium nitrate tetrahydrate is treated with ammonia and carbon dioxide to form ammonium nitrate and calcium carbonate:

$$Ca(NO_3)_2 \cdot 4\,H_2O\,(s) + 2\,NH_3\,(g) + CO_2\,(g) \longrightarrow 2\,NH_4NO_3\,(aq) + CaCO_3\,(s) + 3\,H_2O$$

$$\Delta H = -126\,\text{kJ/mol}$$

The accompanying heat is adequate to evaporate all the water. However, a direct procedure is not possible because of the unfavorable equilibrium at elevated temperatures. In the *BASF process* (Fig. 7), heat removal is separated from the reaction of $Ca(NO_3)_2$ with $(NH_4)_2CO_3$: NH_3 and CO_2 are dissolved in a circulated NH_4NO_3 solution, and the heat given off is removed. The calcium nitrate tetrahydrate is also dissolved in an NH_4NO_3 solution. The two solutions are then reacted at ca. 50 °C; the heat produced is minimal.

Figure 7. BASF process for conversion of calcium nitrate
a) Absorption tower; b) Condenser; c) NH_4NO_3–$(NH_4)_2CO_3$ solution; d) Cloudy NH_4NO_3 solution; e) Reaction vessel; f) Settling vessel; g) Classification filter; h) Belt filter

The grain size of the calcite precipitated can be influenced by the way the reactants are introduced. After reaction the approx. 65 % NH_4NO_3 solution is separated from $CaCO_3$ on a belt filter and concentrated by evaporation. The $CaCO_3$ still contains small amounts of ammonium compounds and phosphate and is mostly used for the production of calcium ammonium nitrate. If the calcium nitrate is suitably prepared before conversion, quite pure $CaCO_3$ may be produced.

For directly converting calcium nitrate and at the same time removing the heat of reaction, Hoechst developed a special vertical reactor [17]. The gaseous CO_2 is introduced at the bottom, and the ammonia is introduced in three zones, each cooled with water.

1.3. Granulation

Pure ammonium nitrate has a nitrogen content of 35 %. Commercial fertilizer ammonium nitrate is produced in several countries with an N content of 34.5 % or 33.5 %. It generally contains additives to stabilize the grain and improve storage properties.

Various processes have been developed for granulation [18], [19]. *Prilling* is preferred for large plants producing upwards of 1000 t per day, while the other processes are also suitable for lower outputs, around 250 t per day. Prilling starts from melts containing around 0.5 % water. Round or rectangular spray towers up to 70 m tall are used. The towers are concrete, steel, aluminum, etc. Steel frameworks and concrete must be coated with protective paints. Figure 8 [20] shows a diagram of an ammonium nitrate prilling plant.

Figure 8. ICI process with prilling tower
a) Ammonium nitrate neutralizers; b) Falling film evaporator; c) Filter; d) Prilling tower; e) Screen

The solution is sprayed through one-component nozzles, perforated plates, or perforated centrifuges at the top of the tower. Cold air is drawn through the tower countercurrently to remove the heat evolved on crystallization. As the droplets fall through the tower, they solidify into round granules, which are discharged at the foot of the prilling tower and subsequently cooled and screened.

There is no need for the granulate to be dried if 99.5 % NH_4NO_3 melt is sprayed. The prilled grain has a 2 – 3 mm diameter, thus smaller than from most other processes. Grain size is affected to a certain extent by the shape of the nozzle, by the perforation cross sections and the rotational speed of the spray centrifuge, and by the viscosity of the melt.

Serious emission problems attributable to ammonium nitrate fumes are often encountered in prilling on account of the large air throughput. Modern plants are generally equipped with special emission control systems. In the CFCA shroud system [21], for example, the cooling air is divided by baffle plates or tubes in the prilling tower into two streams. Only the inner stream, containing most of the pollutants, is cleaned. Usually the off-gases from the neutralization and evaporation stages are also cleaned.

The universally applicable recycle salt process (Fig. 9), developed by BASF in 1928 [22] for *granulating* calcium ammonium nitrate, produces 2 – 4 mm granules. The process can be modified, for example, by arranging a revolving

drum after the paddle screw to improve granulation, by carrying out drying or cooling in a fluidized bed, or by subjecting the granulate to hot or cold screening.

Figure 9. Recycle salt process
a) Granulation screw; b) Drying drum; c) Cooling drum; d) Screens; e) Grinder

The *pan granulation process* has been further developed, e.g., by TVA and Norsk Hydro. Figure 10 [23] shows the plan of the Norsk Hydro process. In the sloping, rotating pan granulator, the 99.5 % ammonium nitrate melt is sprayed onto a moving solid bed and solidifies on the cold particles. The growing granules are graded in the rotating pan and, after reaching the required grain size, roll over the edge. Grain size may be varied by changing the operating parameters: a normal fertilizer grain diameter of 2 – 4 mm and a grain size of 7 – 11 mm for forest fertilization can be made in the same granulator.

Figure 10. Norsk Hydro pan granulation process
a) Dust filter; b) Pan; c) Cyclone; d) Polishing drum; e) Crusher; f) Cooler; g) Screen

Ammonium nitrate can also be granulated in a revolving drum, known as a spherodizer, or in a fluidized bed (e.g., Fisons Nitro-Top process) [24].

In addition to the production of ammonium nitrate containing 33.5 % or 34.5 % of N, each of these processes is also suitable for the production of calcium ammonium nitrate containing 26 % – 28 % N.
